Other evidence, it seems to me, is the result of confounding the potentiality of a function with its manifestation. I allude to one set of examples on account of the interest of the cases, and I do so with the deference due to the eminence and ability of the gentleman who has furnished the evidence. That evidence has been collected under the head of "inheritance of characters due to the exercise of function." The evolution of the American trotting horse was considered. It was recorded that "by 1810 the t[illegible]e for trotting as a sport had . . . increased [illegible] in 1818 it became a recognized sport under [illegible] rules. . . . At the end of 1824, six years [illegible] first accepted three-minute record, the rec[illegible] fallen to 2:34. . . . . By 1848 the record wa[illegible] to 2:29½; the next decade lowered the reco[illegible]nds. . . . Finally, at the close of 1896, the re[illegible] been further lowered to 2:03¾." It is deduced from these premises that "there is nothing whatever in the actual phenomena observed anywhere along the line of this development of speed that would lead us to even suspect that the changes due to exercise of function had not been a factor in the evolution." But to me it seems that there is no evidence to show that the speed attained was other than would have resulted from taking the same animals untrained and then speeding the last. The speed is, of course, simply the expression of functional adaptation, and the horses were selected merely because, by their manifestation, they showed that they had the co-ordination of structural and psychological characters needed for the manifestation of the function. The manifestation guided the breeder to the selection of the animals. The successful animals were the pick of thousands unknown to fame.

But there is much in the history of the development of animals that seems to lead to the belief that eventually modifications may be due in part to acts of representatives of the phylum to which they belong. It is difficult to believe that some structural features are simply the result of natural selection operating on chance variations. An application of the doctrine of chances to some such cases appears to be adverse to the conception that they represent the influence of natural selection unaided.

A feature characteristic of most cave animals of widely diverse groups and classes is the atrophy of the eyes, and it seems to be most logical to attribute this to disuse of those organs in remote progenitors, and to assume that the atrophy may have resulted from a failure of nourishment by the nutrient fluid of the organs on account of the loss of functional activity rather than to selection by nature of forms with successively diminishing eyes. The presence of eyes in most cases certainly would scarcely be an element of disadvantage to animals, and it may be allowable to invoke some other agency than chance selection. We may be justified in postulating that the continuous disuse of the organs would in time react on the nutrition of the parts affected, and finally atrophy or disappearance would result. Like explanation would be applicable to the innumerable cases of atrophy of parts known to the naturalist.

But if cessation of nutrition culminates in final atrophy, increased nutrition of parts may result in hypertrophy and increased nutrition may be the concomitant of increased activity of parts. The exercise of such parts continued for many generations may react on the organization and the progeny at length be affected thereby. Of such cases Cope adduced many examples. The feet of the horse line furnish illustrations. The existing horse has the median toes and hoofs greatly hypertrophied and the lateral ones atrophied, but the remote ancestors had feet of nearly the same general pattern as the rhinoceroses and tapirs. Atrophy of the lateral digits has progressed inversely to hypertrophy of the middle ones. An analogous line of development culminating in feet superficially much like those of the horse was followed by another quite remote family of hoofed mammals, the Prototheriids of South America.

The idea of acceleration and retardation was associated by Cope with the idea that the course of evolution was determined from the beginning of things, and that life, to use his own words, is "energy directed by sensibility or by a mechanism which has originated under the direction of sensibility." He maintained that "consciousness as well as life preceded organism," and he called this conception "the hypothesis of archæsthetism." This idea I refer to especially because it was broached in his vice-presidential address, delivered at the meeting of the American Association for the Advancement of Science, in Philadelphia, in 1884.*

I am myself unable to comprehend consciousness except as a product or result of organization, and those who wish to learn more about Cope's views respecting the question must refer to one of his many papers.

Whatever may be thought of Cope's philosophical views, his presentation of them is always interesting and some of them are illustrated with a wealth of facts that renders his communications valuable as repertories of well digested information. His first special paper, on "The Origin of Genera," published as early as 1868, is especially noteworthy for the mass of morphological data contained in it and for the apt manner in which they are tabulated.

VIII.

I venture to conclude with some reflections on the rank that may be assigned to Cope in the world of Science.

Among those that have cultivated the same branches of science that he did—the study of the recent as well as the extinct vertebrates—three naturalists have acquired unusual celebrity. Those are Cuvier, Owen and Huxley.

Cuvier excelled all of his time in the extent of his knowledge of the anatomical structure of animals and appreciation of morphological details, and first systematically applied them to and combined them with the remains of extinct vertebrates, especially the mammals and reptiles. He was the real founder of vertebrate paleontology.

Owen, a disciple of Cuvier, followed in his footsteps, and, with not unequal skill in reconstruction and with command of ampler materials, built largely on the structure that Cuvier had begun.

Huxley covered as wide a field as Cuvier and Owen, and likewise combined knowledge of the details of structure of the recent forms with acquaintance with the ancient ones. His actual investigations were, however, less in amount than those of either of his predecessors. He excelled in logical and forcible presentation of facts.

Cope covered a field as extensive as any of the three. His knowledge of structural details of all the classes of vertebrates was probably more symmetrical than that of any of those with whom he is compared; his command of material was greater than that of any of the others; his industry was equal to Owen's; in the clearness of his conceptions he was equaled by Huxley alone; in the skill with which he weighed discovered facts, in the aptness of

† Penn. Monthly Mag., 1872; Origin of the Fittest, p. 11, 1887.

* Origin of Fittest, p. 405.

his presentation of those facts, and in the lucid methods by which the labor of the student was saved and the conception of the numerous propositions facilitated, he was unequaled. His logical ability may have been less than that of Huxley and possibly of Cuvier. He has been much blamed on account of the constant changes of his views and because he was inconsistent. Unquestionably he did change his views very often. Doubtless some of those changes were necessitated by too great haste in formulation and too great rashness in publication. The freedom to change which he exercised, and which was exercised too little by at least one of his predecessors, was an offset to his rashness. He exercised a proper scientific spirit in refusing to be always consistent at the expense of truth.

His reputation at present is much inferior, at least among the people at large, to those of the men with whom he has been compared. Immediate reputation depends on various circumstances, some of which are quite adventitious, and it is often long before men find their true levels. It is scarcely premature to prophesy that Cope's reputation will grow, and that in the future history of science his place will be at least as large as that of any of his predecessors.

SOME ELECTRICAL SPORT.

By JAMES F. HOBART.

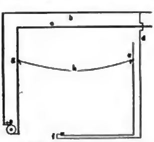
ALMOST any man feels better for having a joke once in a while, and the electrician is no exception to the old adage:

"A little nonsense now and then
Is relished by the best of men."

Electricity offers a vehicle for the conveyance of more uproarious fun to the square inch than anything else man is acquainted with, and it is very easy to rig up things in a dynamo room in such a manner as to more than astonish visitors that may drop in.

But this may be dangerous, especially where an arc light current is used, unless proper precautions are taken, and the young engineer or electrician who is prone to practical electric jokes should never try anything in this line that is new to him, unless he has first talked over the matter with an experienced electrician and fully discussed the matter with him. Such a course may prevent accident, and the experiments will not lose anything by having competent advice given.

Some things may be done which form very striking illustrations of electric energy and yet do not come strictly within the meaning of the words "sport" or "fun." In Fig. 1, let a represent an arc dynamo and b



AN ELECTRIC FLASH LIGHT.

and c the leads that pass to the lamps outside the dynamo room. Take off a branch wire as shown at d. Lead this wire to a convenient part of the room and terminate it with the small hook shown at e. A switch, f, may be located at any convenient part of the room. In a rig put up by the writer it was located in the floor, close to the engine, where a man would naturally stand when attending to that machine.

The negative lead had its insulation removed at g, and another hook attached there. A piece of No. 36 copper wire was stretched from one hook to the other as at h.

The length of wire must be determined by experiment. If too long, the experiment will be unsuccessful. About 15 to 20 feet will be about right for a first trial. Arrange the hooks so the wire will hang just above the head of the tallest person likely to come under it.

By closing the circuit at f, the current will flow through the fine wire, and if the voltage is high enough, the wire will be burned with a flash like that of lightning. It forms a very striking experiment in the heating of conductors, and if 15 or 20 feet of wire is burned just above the heads of visitors, some of them, especially the ladies, are apt to be heard from at once.

By putting in a wire heavy enough so that the dynamo cannot flash it instantly, the expansion of metals will become apparent, as the wire will sag 2 or 3 feet when current is turned on before it gets hot enough to burn. If the size and length of wire be gaged just right, current can be turned on and the wire will stretch to its limit and contract again when current is cut off. Or, by making short contacts carefully, the fine wire can be stretched and contracted and then burned with a flash at will. In a following article an account will be given of how some street urchins were cured of hanging around an electric light station.—American Electrician.

To Clean Paintings.—To clean an oil painting, take it out of its frame, lay a piece of cloth moistened with rain water on it, and leave it for awhile to take up the dirt from the picture. Several applications may be required to secure a perfect result. Then wipe the picture very gently with a tuft of cotton wool damped with absolutely pure linseed oil. Gold frame may be cleaned with a freshly cut onion; it should be wiped with a soft sponge wetted with rain water a few hours after the application of the onion, and must finally be wiped with a soft rag.—Der Stein der Weisen.

ELECTRIC TRACTION AT PARIS.

ELECTRIC traction is not making rapid progress in Paris. While in foreign countries and in country towns we daily see new installations of electric tramways established and very rapidly developed, we remain in Paris with a few lines provided with accumulator cars and with a single line having contacts with the surface of the earth. The question of aerial or subterranean conductors is, in fact, of high importance, and does not seem as yet upon the point of being solved.

Meanwhile we shall make known the new arrangements adopted by the Society of Tramways, of Paris, and the Department of the Seine for the lines that run from the Madeleine to Courbevoie, to Courbevoie-Neuilly and to Levallois, and that have the respective lengths of 4, 4½ and 3½ miles.

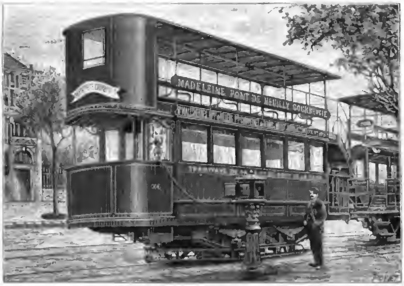


FIG. 1.—VIEW OF A CAR IN THE PROCESS OF BEING CHARGED.

The system adopted is electric propulsion by rapidly charged accumulators. The charging is effected in a few minutes and during the period of stoppage at the termini of the road.

The installation that we are about to describe was made by the Société Industrielle de Moteurs Electriques et à Vapeur.

The generating works are established at Quai National, at Puteaux. They contain three Babcock & Wilcox multitubular boilers capable of furnishing 3,960 pounds of steam per hour at a pressure of 245 pounds to the square inch. These boilers supply three Willans triple expansion steam motors, each directly actuating a four pole Brown dynamo of 300 amperes and 600 volts at an angular velocity of 400 revolutions a minute. The steam engines are capable of running with escapement in open air or condensation. The water necessary for the condensation and the supply of the boilers is taken from the Seine by a pump actuated by an electric motor.

Fig. 3 gives an internal view of the engine room of the works. To the left are situated the three groups of motors with coupled dynamos, and to the right the distributing board. Each dynamo is connected with a special panel by a circuit that traverses two circuit breakers and a bipolar interrupter.

From the distributing bars start six feeders, one of which is designed for supplying the charge to the depot, two for actuating the electric pumps and assuring the lighting, and the three others for charging the cars at a distance. Each of the circuits traverses upon the board an automatic lever interrupter, an ampere meter and two circuit breakers.

Of the three feeders, one, of a section of 0·25 square inch, does duty for the charging station at Courbevoie-Neuilly; the second, of 0·25 square inch section, is connected with Courbevoie (Place Victor Hugo); and the third ends at Levallois, upon the edge of the Seine. They are formed of lead-covered cables placed directly on the ground.

At each charging station there is installed a post of a form analogous to that of fire alarms. The feeders are connected with a small internal board, and a collector permits of putting the post in connection with the car (Fig. 1).

The cars have a seating capacity for 52 passengers and are double decked. Each weighs in running order 14 tons and is capable of hauling a trailer of 7 tons. It contains 200 Tudor accumulators, each with five 42 pound plates placed under the seats in hermetically closed boxes. Fig. 2 gives a view of the space beneath the seats in which the accumulators are placed.

The charging is done with a constant difference of potential. The battery, all the elements of which are mounted in tension, is put in communication with the charging station through a small board that may be seen in front in Fig. 2. The mean intensity of the charge is 120 amperes and the duration from 10 to 12 minutes.

Each car is provided with two motors of 25 horse power, each revolving 500 times a minute and actuating each of the two axles through a steel pinion and a cast iron wheel. The running speed allowed by the regulations is 9½ miles an hour outside of Paris and 7½ miles

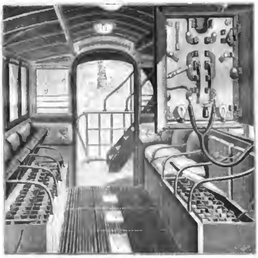

FIG. 2.—INTERNAL VIEW OF A CAR, SHOWING THE DISTRIBUTING BOARD AND ARRANGEMENT OF THE ACCUMULATORS.

within. Let us add that the car is provided with a controller that permits of effecting all the maneuvers and suppressing a battery, if an accident should happen. Upon a normal run all the accumulators are coupled in tension. In addition to the rope brake maneuvered by the winch of the controller, each car is provided with screw brakes and sand boxes. The car is lighted with six electric lamps branched in tension upon the battery. Two small electric fans serve for driving to the exterior the gases disengaged during the charging.

These few data, although very incomplete, show us

that it is a question in Paris of an interesting experiment that will give an idea of the practical value of propulsion by means of Tudor accumulators. Some interesting results have already been obtained at Hanover. —La Nature.

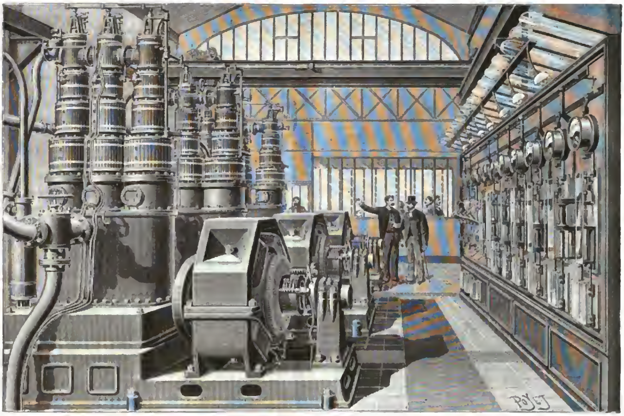

FIG. 3.—INTERNAL VIEW OF THE MACHINERY HALL OF THE WORKS FOR THE PRODUCTION OF ELECTRIC ENERGY.

LIGHTHOUSE PROGRESS, 1887-1897.

IN 1887 some account was given in Nature of lighthouse work and progress in the United Kingdom during the preceding fifty years. I propose in this article to consider briefly the same subject in connection with the past ten years, so that the whole may form a summary record of what has been attained during the Victorian era in this important branch of optical and mechanical science.

And, first, it may be asserted that the period of the Queen's reign, distinguished as it is for so many developments of new industries, can boast of none more valuable or more interesting than this now in question. Fresnel's monumental invention in 1819 of the dioptric system of lights was at once welcomed and realized by the French government, who have since always encouraged and supported the native constructors of lenticular apparatus. But it was only after thirty years from this date that the lighthouse industry was planted in England, if we except the experimental attempts of Messrs. Cookson, of Newcastle. The systematic and permanent establishment is due to the public spirit and the enterprise of Messrs. Chance Brothers, subsequently aided by the mathematical talents and personal direction of Mr. James T. Chance, whose services to the Royal Commission on Lights of 1860, as well as to the Trinity House, and whose writings on lighthouse optics, are widely known. It is said that great pecuniary loss resulted from the first efforts of Messrs. Chance, but they have gone on steadily and alone to the present day, with little or none of official aid or encouragement, and they are certainly entitled to full credit for having done so much and so well for the coast illumination of their own country and the world.

I adopt the main divisions of the former articles, viz., Towers, Apparatus, Lamps.

There is not much to be noted in regard to the architecture or engineering features of the iron and stone lighthouses erected in Britain during the past ten years. The principal island towers are in the Shetlands, viz., Stroma, Fair Island, and Sule Skerry, which is one of the dangerous reefs known as skerries so thickly strewn on the northern and western coasts. These all are the successful works of Messrs. D. and C. Stevenson. The Trinity House has not erected any rock or pile tower since the Round Island in 1887.

Of lightships there have been established two only, which are at the mouth of the Thames to mark the Edinburgh Channel, and, like all the Trinity lightships, they have 21 inch silverplated reflectors, with the powerful two-wick oil burners of Sir J. Douglass, the flash from one face of the light being equal to 20,000 candles.

To nearly all the light vessels in our waters sound signals, chiefly of the siren type, have been added, which are invaluable in the frequent sea fogs that beset our shores, since by a marvelous beneficence of nature —for the proof of it we are chiefly indebted to the researches of Tyndall—fog that quenches light deepens the intensity of sound. The siren is now an indispensable adjunct to our principal land lights, and a visit to the Isle of May, the St. Catherine's, or Ailsa Craig, would well repay any one desirous of seeing the latest and best arrangements for the production and transmission of its weird and inimitable notes.

Many of our land lights and floating lights have been connected with the main telegraphic system "for life-saving purposes only." There were, at the end of 1896, 27 such stations in England and Wales, 14 in Scotland, and 11 in Ireland. The most suitable places were selected for the observation of passing vessels and for the immediate transmission of reports of casualties to the nearest points available for help. It is by no means an easy work to make a durable telegraphic connection with a lightship, and with all stations the cost is considerable; but the benefit is so marked that this communication, long and urgently demanded, will soon be extended to all other sites on the coast where the advantage is evident, and the difficulty not insurmountable.

Of the new sea lights in the decade under review may be mentioned the Girdleness, the Rattray Head, the Tarbetness, the Stroma, the Seaddon, the Skroo, and the Sule Skerry, all on the Scottish coast, and the Round Island, the St. Catherine's electric, the Spurn Point, and the Withernsea, on the English coast. The characteristics of several older lights of fixed sections have been changed, such as the Whitby, Coquet, Orfordness, Southwold, and Needles, which have been made occulting lights.

To complete the bare statistics of the subject, it may be mentioned that the whole number of lights of all sorts and sizes on the coasts of the United Kingdom on December 31, 1896, according to the Admiralty List, was 1,095, an increase of about 200 over the number of ten years ago. Of the 1,095 lights, not more than 11 or 12 per cent. may be classed as of sea power, and 6 or 7 per cent. as lightships. The rest are port, harbor and pier lights, showing a very abundant supply of local signals apart from the great coast signals controlled by the three Lighthouse Boards.

It would seem, indeed, that the programme of coast lighting is almost completed—at least as regards England. A powerful oil light is to be erected by the Trinity House in St. Mary's Isle, on the northeast coast, and two others in Lundy Isle in the Bristol Channel, where also, at Lynmouth, an electric light is proposed. A further improvement in the fine reflector light of Beachy Head is also spoken of. The Northern Commissioners will erect a first-class light at Noup Head, in the Orkneys, and another on the Flannan Islands in the Hebrides. For Ireland no new light appears to be intended for the present; but the improvement of the Fastnet, the most outlying of our lights westward, must soon be taken in hand.

The lantern which crowns the tower and protects the apparatus of a land or rock lighthouse has been materially improved in its construction. The perfect lantern is of adequate area to contain the light and accessory parts, and afford convenient space for service. Its diameter for a sea light is rather 14 feet than 12 feet. It is of circular form throughout, having a cast iron pedestal of sufficient height to carry an inside and an outside gallery for cleaning purposes. The framing is of gun metal or wrought iron. The half inch plate glass of the purest quality, while resisting wind and weather to a great extent, intercepts the least possible light from the lenses. There is provided abundant ventilation to sustain the central lamp, and refresh the keepers. The best contribution of the Trinity House to the structure has been the large cylindric ventilator on the double copper dome, by which the last named advantage is mainly secured.

Turning to the optical features of the decade, let us see what changes have affected the two main factors of illumination—the fixed light and the revolving light. The ever-increasing number of ships and ports, and the sustained demand for greater and greater speed of vessels, and for sea signals that shall serve more and more to meet all conditions of weather and to discriminate harbors and channels of approach, have stimulated the efforts of lighthouse engineers in the two directions of power and distinctiveness.

The characteristics introduced of late years have been confined for the most part to new combinations and periods of group flashes, or of single equal flashes. Mixed lights of fixed and revolving sections, and therefore with unequal degrees of visibility, are no longer in good repute, although, in the French service especially, they are still retained. Color also is being gradually abandoned for sea lights. For harbor lights, however, it is still freely resorted to, most of all in Northern Europe, as in the Oland light, Baltic Sea, where in one small apparatus there are no fewer than six characteristics with seventeen variations.

Power has been sought:

(1) By the substitution, wherever practicable, of annular for cylindric lenses, or of revolving for fixed sections.

(2) By the longer focal distance and larger condensing surface of these lenses, and by superposing them in vertical series.

(3) By using an illuminant of maximum intensity, whether oil, gas, or electricity.

(4) By certain variations and extensions of the Fresnel refractors, giving a higher coefficient of beam.

(5) By invoking the principle of the full perception of the light from an annular lens moving in rapid rotation with very short intervals between the flashes. This is known as the feu éclair.

(6) By rotating an opaque screen around a lamp, or by raising and lowering quickly an opaque cylinder, or by cutting off and relighting of gas in rapid alternation.

Let us consider these in order.

(1) The reasons for the disuse of fixed sea lights, except in the case of marking or intensifying particular sectors, are chiefly their want of power to penetrate to their natural horizon, and the increasing number of bright fixed lights on ships and on shore, which may in certain conditions lead a navigator into danger from the difficulty of distinguishing them from a lighthouse. The flashing light, with its superior power and numerous possible distinctions, is the best safeguard against this.

(2) The hyper-radial lens of 1,330 millimeters focal distance, first suggested (as Prof. Tyndall declared) by Mr. John Wigham, and concurrently at least by Mr. Thomas Stevenson, who less fitly termed it hyper-radiant (a good name for the ten wick oil flame, or ten ring gas flame), has quite justified the expectation of lighthouse engineers as a convenient and powerful instrument admirably adapted to the large burners now employed. This lens, like its predecessor of 920 millimeters radius, is commonly used without catadioptric prisms, as in the Spurn Point light. The disuse of prisms effects a great saving in cost at but an inconsiderable diminution of power where a high vertical angle of refraction is adopted. Yet it must be admitted that this is at the expense of symmetry and elegance. The French light on Cape d'Antifer is a fine example of the hyper-radial system, embracing a full complement of prisms.

There has also been constructed, at Mr. Wigham's

suggestion, as an experiment, what he aptly calls a giant lens of 2,000 millimeters radius, but it is not yet adopted in practice.

The superposition of lens lights, each with its own burner, is an obvious means of gaining power, and it is remarkable that, although first suggested in 1859, it was not practically utilized with dioptric apparatus until 1872. Whether biform, triform, or quadriform arrangements be resorted to, the advantage of concentrating or reducing the intensity of the beam according to atmospheric variations is inestimable, and the adaptation reflects undoubted credit on Mr. John Wigham, whose polyannular gas burner on a like plan had been already approved. The triform Tory Island light, fitted with these burners, and variable in power from 17,500 to 393,500 candles, may be cited in illustration.

(3) The maximum intensity of an illuminant must still be sought in the electric arc. Gas and oil remain substantially equal compared in lamps of the same size and sort, the superior applicability of each being determined by local conditions. In Ireland the Wigham expanding burners give a marked prominence to the gas, which is copiously used in them. In England and Scotland mineral oil is preferred, its quality being carefully maintained at the highest standard. The old disability of this illuminant, the risk of explosion, has been almost nullified by the production of a petroleum whose flashing point is 230°, and long experience has confirmed its great value. On the other hand, the gas called "incandescent" has been introduced, the best form of it being of the Auer-Welsbach type. The brilliancy of this gas is perhaps only second to that of the electric arc, but the perishable character of its accessories exacts great caution in using it, and it has not as yet been employed in any sea light in this country, although it is already so adopted in France. A mixture of oxygen and coal gas, and one of oxygen and oil vapor, which have been tried in street lamps and otherwise, have been recommended for lighthouses, but not hitherto accepted.

Electricity has been, as it were, on its trial since the South Foreland experiments of 1885, and the evidence affecting it is hardly yet complete enough to justify a final verdict. The result established at the South Foreland was that the electric light is the most powerful under all conditions of weather, and has the greatest penetrative intensity in fog. The committee of the Royal Society, which examined in 1890 this report of the Trinity House, found that the experiments did really justify the results given.

The twelve years that have elapsed since the trials at the South Foreland have on the whole tended to qualify the conclusion as to the penetrative power in fog. Three lights—two of the group flashing and one of the single flashing character—constructed by Messrs. Chance, may be cited on this point. The triple flash of the Tino light (near Spezia) has been unmistakably discerned in rain and fog at a distance of more than twenty miles. On the other hand, the Isle of May light has been invisible in a thick atmosphere not amounting to fog, at a distance of twelve miles, and in a dense fog at half a mile; and the St. Catherine's light was equally invisible to the Eider before she grounded on the Atherfield ledges. It has been, indeed, asserted that the St. Catherine's has often been unseen at a quarter of a mile distance.

The truth appears to be that the electric light is very sensitive to atmospheric conditions, which are so many and so various, and that in thick weather it parts with its power in a much greater ratio than does a gas light, or even an oil light. There is a degree of fog which quenches the sun, while the large luminous surfaces of the superposed gas lenses project on the fog a reddish coloration, and the fog itself thus becomes a signal to the mariner when, as it were, in the words of Persius, "Pinguem nebulam vomuere lucernae." It would be most dangerous, however, for the mariner in a fog to approach the coast presuming on this quality of a light in whose vicinity he supposed himself to be. The lead, the anchor, the horn, should be his trust till the veil lifts, and the electric beam shines out in full splendor.

There has occurred no important change in the burners of sea lights. The Trinity House improved six wick, or rather five wick, remains, if not the largest, the best working oil burner, with a power of 800 candles. This is used generally for lights of the first and second order, while the four wick, with a power of 300, is used for third order lights, and the eight wick, of 1,200 candles, for hyper-radial lights. The lamp is of the "pump" or the "pressure" type, and contains from 10 to 100 gallons of oil. It is probable that, owing to considerations of space and economy, the gravity system may again be resorted to with enlarged reservoirs seated on the lantern roof. The electric arc is used with carbons of from 15 mm. to 65 mm. diameter and currents of from 50 to 400 amperes. The incandescent filament is not found equally appropriate. The luminous intensities obtained from the arc range from five to fifty thousand candles. Both direct and alternating machines are employed. The installations at St. Catherine's and the Isle of May are of the most complete character, and do honor to the distinguished engineers of the Trinity House and the Northern Commissioners.

It may be mentioned that for positions difficult of access, lamps having special wicks and reservoirs for oil or gas, capable of burning from ten to thirty days, are now in use, though, of course, these are only available for small isolated lights.

(4) The improvements since 1887 in dioptric lights are few, and, with one exception, are of no striking importance. The great invention of Fresnel, perfected by the beautiful holophotal arrangements of Stevenson, has remained the cardinal principle of all modern lights of the lenticular type. But the inevitable tendency to modify and improve has resulted in several proposals of more or less merit. Mr. Alan Brebner had, in 1882, submitted an ingenious plan for producing vertical and azimuthal condensation by single agency in cases where straight prisms placed outside the main apparatus had been employed to intensify one or more sea sectors. This method, however, has been seldom, if at all, adopted. Again, Mr. Brebner, in 1884, had recommended a plan of dipping a portion of the beam to some intermediate distance between the lighthouse and the horizon to meet the case of a fog which the strongest beam can only very partially penetrate. This, or some analogous plan, has been tried, but has not prevailed. The advantage of withholding from the horizon a substantial part of the beam, and deflecting it anywhere, is extremely doubtful. The depth and direction of a fog are always uncertain elements. The lighthouse may be surrounded by it while the offing is clear, or vice versa. And it would be in equal measure mischievous to encourage the mariner to stand in, looking for a signal which he might never see, or see too late; and to intrust the lightkeeper with the power to deflect the light according to his own judgment. In 1892, Mr. Charles A. Stevenson published in Nature an account of his spherical and equiangular refractors which remedy a certain loss of emergent light in the Fresnel refractors. In 1894, Mr. Stevenson further developed his design, claiming for it, within practicable limits, an advantage of at least 10 per cent. in increase of light as compared with the Fresnel lens. The improved refractors have been adopted with success in several of the Scottish lighthouses. In 1895 and 1896, Mr. John A. Purves contributed an able mathematical analysis of equiangular prisms and a new form of spherical central lens, called the inverse refractor (the facets of the lens turned inward), to be used in connection with Mr. C. Stevenson's equiangular prisms. Messrs. Chance have raised the Fresnel lens from 57° vertical to 80°, using glass of the same refractive index, and this angle has been adopted by the Trinity House with great advantage.

(5) The one exception referred to in regard to the minor improvements of optical apparatus since 1887 is the "lightning light," an adaptation of serious importance which has attracted the attention of lighthouse engineers in nearly all maritime countries. The shortening of the interval between the flashes of a revolving light, so that the mariner, especially when in a fast liner, may have more speedy cognizance of the signal that guides him, has become a plain necessity, and led to the gradual reduction of the period from 60, 45 and 30 seconds to 20, 15, 10, and even 5 seconds, reducing proportionately the duration of the flash. So far the principle of the feu éclair has been approached. But much more than this is demanded. No one has advocated more strenuously than Lord Kelvin, himself a sailor and a benefactor of sailors, the acceleration of revolving lights. No one has laid it down more clearly that one-ninth or one-tenth of a second is sufficient for the eye to receive the full luster of a lens passing it. Any longer duration is a loss of time, and therefore of intensity. German and French physiologists have confirmed this, and it is the principle on which the feu éclair system is based. In its application, then, if for any "order" of light the maximum of power be desired, the largest available lens in vertical and horizontal angle, combined with a totally reflecting mirror and a central flame of adequate dimensions, must be adopted. If two or more lenses be used, singly or grouped, the intensity of each flash is proportionately less, the interval of time, say five seconds, between the single flashes or the groups of flashes being the same as where there is only one lens. In this manner the greatest intensity and the shortest interval are secured, and the characteristic as presented to the mariner seems theoretically perfect. The first general introduction of the "lightning light" is due to M. Bourdelles, the chief of the French lighthouse administration, under whose auspices several lighthouses on the coast of France have already been endowed with it. In England Messrs. Chance have constructed in 1895, for Cape Leeuwin, Western Australia, a "bivalve" apparatus of the first order, with an experimental duration of beam of one-fifth of a second, and they have placed, this year, in the exhibition of the Imperial Institute a "univalve," or one-lens apparatus, of the third order. Both these lights are on the feu éclair system.

Successful as this system appears to be, it should for the present be regarded as on its trial, and as awaiting the collective judgment of mariners on certain points. And meanwhile it should be estimated as supplementing, not displacing, the well tried forms of apparatus at the disposal of the lighthouse engineer.

A notable adjunct to the new rapidly rotating lights is the mercury float carriage, by which the effect of weight and friction is largely diminished. Another excellent quality of this arrangement is its suitableness for stations where earthquakes prevail, as it provides an elastic connection between the optical apparatus and the pedestal, instead of the rigid bearings in the older forms of carriage. If the Cammuilla lighthouse in Chile had been fitted with the mercury float, it is probable that it would not have been wholly ruined by the shock.

(6) The principle of occultation, that is, of interrupting the fixed beam of a cylindrical lens of an oil light by a dark shade moving round or over the flame, or in a gas light by cutting off the gas, is acknowledged to be of extreme usefulness, and has been applied to many of the fixed lights of our coasts. It is not that any power is really added to the light, but that the quick alternation of light and dark in various groups or periods imparts a quasi-intensity to the beam and a valuable set of characteristics for the mariner. The law of contrast has a physiological effect here, as it has in another manner with the feux éclairs. It is an extreme example, but it rests on trustworthy evidence, that the occulting light of Ventotene Island, near Naples, which is of the sixth order only, has been seen from a distance of nineteen miles, its normal range being nine miles. Using the words of Cicero with another application, it may be truly said, "Eo magis elucet quo magis occultatur."

Investigations into the amount of light reflected and transmitted by certain kinds of glass—lighthouse glass among the rest—have been most ably conducted by Sir John Conroy, Bart., at Oxford, in 1888. He traversed by newer methods and with surer results the ground of many observers, from Augustin Fresnel to Lord Rayleigh; and he demonstrated that "the values of the transmission coefficients for light of mean refrangibility show that for one centimeter the loss by obstruction amounts to 2·02 per cent. with crown glass and 1·15 with flint glass." The refractive index of lighthouse glass lying between 1·52 and 1·54, the loss may thus be practically taken as 2½ per cent. for ten millimeters of thickness.

The intensities of lighthouse apparatus have of late been diligently considered by lighthouse authorities with the view of determining once for all the relative values of the six orders of lights, and of the lamps appropriate to them, and also of publishing the results in the Admiralty Light list. A large amount of uncertainty and misconception seems to have prevailed on this question. M. Allard, in 1876, in a celebrated memoir, gave an elaborate exposition of the whole subject, but his conclusions, always tending to excess, have not been accepted by more recent investigators.

Other estimates, official as well as private, and more or less discordant, have from time to time appeared, both in this country and France. The factors of evaluation, such as radius, lens surface, vertical section, flame, reduction for losses, etc., have been combined in different ways by different persons, and some of their conclusions must be regarded as merely empirical. But in 1891 and 1892 a serious attempt was made by a committee of the chief engineers of the three lighthouse boards to compile an accurate schedule of intensities with photometry as a basis. Taken as a whole, the values arrived at are fairly acceptable, not certainly erring on the side of excess.

But as yet only the lights with oil or gas for illuminants have been determined.

Electricity appears even more difficult to deal with, and no intensities have been assigned officially to any of the electric lights in the British Islands.

Thus it is uncertain whether, for instance, we are to consider the Isle of May as of six millions of candles or of twenty-six millions, both estimates resting on competent professional authority. The lights on the feu éclair system, oil and electric, are obviously less amenable still to formulæ which may give their coefficients of intensity, although French writers do not hesitate to define these, and deduce thirty or forty millions of candles as "ayant la consécration de la pratique."

It is much to be desired that as a sort of sequel to the publication of the intensities of lights—at all events, of the British lights—there should be provided a form for every vessel under the control of the Board of Trade, in which a return should be made of the appearance of every light approached or passed, with statement of the weather, distance, name and character of the light, etc. These returns, duly kept and handed to the Board of Trade on the first opportunity, would gradually constitute an invaluable record of the merits or demerits of our lights, instructive to the engineer, and through him beneficial to the mariner. I have repeatedly, but in vain, urged this expedient on the authorities.

The administration of lighthouses in this country has undergone no change in the past decade, nor, indeed, since 1861, when the royal commission on lights recommended that a central board should be constituted instead of the quadriform government then, as now, in force, and gave excellent reasons for the recommendation. The further experience of thirty-six years has amply confirmed the earlier conclusions on this subject and has brought into stronger relief the example of the French administration. Some slight approach to the desired reconstruction may be indicated in the report of the committee of inquiry on the mercantile marine fund of 1896, paragraph 71, in the following words: "From the evidence brought before us, we unanimously recommend the formation of a small committee containing representatives possessing as far as possible nautical knowledge, of the Trinity House, the Scotch Board and the Irish Board, which should be summoned at least once a year to advise the Board of Trade upon the desirability of all new works, whether in respect of lighthouses, steamers, buoys or signals, together with all renewals, alterations and important repairs."

But however we may regard the system of government of our lighthouses in contrast with the French system, and desire its amelioration, it is impossible to deny that the United Kingdom has, during the Victorian era, produced men who individually have done fully as much in every part, theoretical and practical, of lighthouse science as have the distinguished men of the sister country. In one group we can point to the names of Faraday, Airy, Thomson and Chance. In another to those of Stevenson, Douglass, Hopkinson and Matthews. In yet another to those of Farrar, Nisbet, Sydney, Webb, Trevor, Wharton and Nares.

These men have enriched and illustrated lighthouse mathematics, engineering, optics, mechanics and nautical and general administration in a manner and with a success to be gratefully remembered in our day and never to be forgotten in the new developments of the years to come.—J. Kenward, in Nature.

INTERDEPENDENCY OF INVENTIONS.

THE advent of important and valuable inventions is often dependent, not upon the brilliant inspiration of some individual inventor, but upon the general and gradual advance of the state of the art to which they belong, making their occurrence not only possible, but almost inevitable. The bicycle is an excellent example of this kind of growth in mechanical construction, since, while it is one of the most important things both mechanically and commercially which has ever been producted, it owes its development to the parallel improvement in metal and rubber working, without which it could never have existed at all, in the modern sense, or to any extent. The clumsy wooden velocipede would always have remained a useless toy had not the introduction of drawn steel tubing made the construction of a light and yet strong frame possible, while the original leather tire of Dunlop could never have led to the practical application of the pneumatic principle without the substitution of the rubber construction which only the advances in rubber manufacture made possible. This is but one instance of what is apparent in many other lines of work, and there is little doubt that if the patent records of the past fifty years were thoroughly studied by competent specialists many inventions, which at the time of their conception were failures simply because of the impossibility of executing the ideas, would now be found both practicable and valuable.—Cassier's Magazine.

Bamboo is used almost exclusively for furniture. It is, however, an excellent material for making scaffolds for building. It decays neither in water nor in the earth, and is rendered harder than ever by dryness. It is also very strong in proportion to weight. Stems 4 inches thick may be used for scaffolds 25 feet high, and will bear the weight of iron beams weighing twenty hundredweight. The length of the stems, too, is a great advantage; some of them grow over 65 feet high.—Wiener Gewerbe Zeitung.

ENGINEERING NOTES.

Seven of its small and obsolete steamers have been sold by the Norddeutscher Lloyd to another Bremen steamship company for a million and a quarter marks. This sum means over thirty dollars a ton, a high price for old steamships.

It is reported that in the year 1896-97 there were seven accidents on Indian railways for every 100,000 train miles run, the number being the same as in the previous year. The proportion of passengers killed, however, was considerably greater, being one in 9½ millions, as against one in 19 millions.

On the London and Northwestern Railway alone there are 17,000 signals lighted every night, says The Engineer, and an engine driver working from Crewe to London and back for his day's work is controlled by no less than 570 signals, to say nothing of those coming under his observation which do not affect the working of his train.

The deepest pit in the world is that at Pernschowitz (Silesia, Germany), which has a depth of over 6,500 ft. below the surface. It has been found by experiment that the temperature in this pit rises by 1° Centigrade for every 143 ft., being 12° at the top and 63° at the bottom. This result agrees with those obtained in similar cases.—La Science en Famille.

Compressed air is now being used by certain American tool makers for performing the feeding, etc., of automatic machine tools, says Engineering. In a screwing machine made by the Acme Machinery Company, of Cleveland, O., the whole of the tools are thus effected. The attendant has only to place the blanks in position, when the machine does all the rest. Very rapid work is thus accomplished, some 7,300 ⅝ in. bolts being threaded in nine hours with a machine having two screwing heads. The same agent is used by another American firm for operating the feed motions and reversing gear of large planing machines. Shifting belts are thus avoided, with the constant wear and tear.

In regard to riveting with compressed air, the master mechanic of the Santa Fé road is quoted as saying that by the use in the Santa Fé shops of a stationary riveting machine three men are enabled to drive 2,000 rivets per day of ten hours at a cost of $4.75, as compared with 200 rivets per day at a cost of $5 by hand labor; the truck riveters—the machine being operated by two laborers at a total cost of $3 per day—drive 3,000 rivets, as compared with 175 rivets driven by hand labor by three men in a day at a cost of $6, while the staybolt breaker makes an average saving of $8 a day and the tank riveter an average daily saving of $10. Further, the mud ring riveters will drive as many rivets as can be handed to them and will make a saving of $12 to $15 a day for that class of work. Not only is this method credited with the great saving named, but it is declared to insure every rivet hole being filled entirely and insures tight work, while of hand-driven rivets in mud rings a large percentage invariably leak.

In using a graphite crucible the first step is the annealing. When the crucible comes from the kiln, where the temperature is very high, it is supposably "bone dry." It is, however, porous, and easily absorbs moisture; hence it should always be stored in a "bone dry" place. As to annealing, both too little and too much stress can be laid on it. The best annealing is even heating. That is, evenly warm the pot, not on one side only but around the pot, to between 250° F. and 300° F., and maintain that heat there until all moisture is expelled. Nothing more is required, except equally good attention should be given to the even cooling all around the pot. The pith of annealing, according to a correspondent of The Engineer (New York), is that the crucible should be heated and cooled off evenly, and receive heat enough and no more than enough to expel its accidental moisture. If the crucible is a large one, after toasting its outside walls, set it over a black, low, slow fire, bottom side up, so that the inside walls, as well as the outside, can get the benefit of the toasting process.

According to a return just issued in the form of a blue book, more than 99 per cent. of the engines and carriages belonging to the different railway companies of the United Kingdom are fitted with a continuous brake, the brakes being not only continuous but also automatic, and constructed in compliance with all the official conditions, says The Engineer. Less than eight years ago more than 10,000 railway vehicles were fitted with brakes which satisfied only some of the demands made by the department, whereas the number has now shrunk to a little more than 20. After allowing for less than 500 vehicles having no continuous brake, perfect or imperfect, we come to a grand total of more than 65,000 carriages and 12,000 engines fitted in the manner prescribed. The extent to which the approved brakes are employed is shown in an interesting form by a statement as to the number of miles run by trains so equipped. In the last six months of 1896 the miles traversed exceeded 100,000,000, being more than 99 per cent. of the total. The Great Western and Northwestern trains each run more than 11,000,000 miles under such conditions.

The Norfolk and Western Railway has equipped its baggage cars with an arrangement of safety bars and hooks for supporting bicycles at the top of the car out of the way of other baggage. Wrought iron holders covered with rubber hose are fastened by screws to blocks placed between the car lines in the center of the roof. These holders are spaced in pairs 3 ft. 8 in. apart throughout. Straps are fastened to either side of the car, central with each pair of bicycle holders, and safety bars are placed across the top of the car between each set of holders and straps. In loading bicycles they are inverted, and the holders in the center of the car roof are hooked into the rims of the two wheels. The frame of the bicycle is then tilted up toward the side decks, the strap being wrapped a few times around the frame, after which its end is slipped over the hook, thus holding the wheel in place. A small stool is carried in each baggage car, by the use of which the straps are easily reached. There is provision in the long baggage cars for carrying 16 bicycles, in the short baggage cars for 12, and in the combination baggage and passenger cars for 8 bicycles.

ELECTRICAL NOTES.

England is secretly laying a military cable between Vigo Bay and Gibraltar, according to the Paris Matin.

After considerable deliberation, the tramway company of Boulogne-sur-Mer (France) has decided on the adoption of the trolley system with overhead conductors.—L'Industrie Electrique.

At Santiago (Chile) a great enterprise is planned. By utilization of the force of a waterfall the whole town is to be supplied with electric light, and the tramway system is to be installed after the present means of locomotion are discarded.—L'Industrie Electrique.

A prominent water wheel manufacturer in San Francisco, according to the Electrician, has recently contracted with a Kobe firm to supply three 500 horse power Pelton impulse water wheels, to be operated under a head of 200 feet. The water wheels will be direct connected to General Electric generators, which will furnish power for an electric railway in Kobe. The contract was secured in the face of severe competition with prominent German and other European firms.

The electric colored fountains at the Brussels Exhibition are now working satisfactorily. The installation is hidden underneath the reservoir, and there are some forty-eight hand projectors used. These throw the light vertically upward through openings which are glassed over. The central space is surrounded by lead pipes, from which 150 jets throw the water to a height of from 7 to 8 yards. These being lit up from underneath by different colors alternately blending, produce an ever varying effect with brightest hues.

Electric Power for Weaving.—At present 1,200 looms at St. Etienne are driven by electrical power, distributed by the company there. The charge is $2 per month, and it is found that hand looms, after conversion to suit them for electrical power, can produce 25 per cent. more work, with a great lightening of labor. The success of this scheme, says The Engineer, suggests the possibility that cheap electrical power in this and other countries may be the means of enabling aged and weak persons to undertake work in their own dwellings.

An electric system of railway signaling, invented by Mr. W. S. Boult, which is now being tested in daily working on the Manchester, Sheffield and Lincolnshire Railway, near Dinting station, promises to be of great importance. It is, says the Builder, a very simple one. An electro-magnet on the road actuating two needles in a box below the engine, and each of them completing a circuit, works two miniature semaphores in front of the driver, and at the same time rings a bell. The signalman is thus enabled to have direct communication with the driver and guard even when the train is at full speed. If this system stands the test of further experience, it will make semaphores and colored lamps superfluous and do away with the present barbarous system of fog signaling.

At the Société de Biologie, at Paris, Dr. Luys read a paper describing experiments made by him, showing the presence of luminous emanations which surround the human body, and he demonstrated it in the following manner, says the Electrical Engineer: In the dark room, place your fingers for about twenty minutes on an ordinary photographic plate which is itself in a bath containing the usual solution of hydroquinone, and after this exposure fix the negative in the usual way. You will see not only your fingers and the lines on the skin reproduced, but also their pores, and, what is still more interesting, round the fingers a sort of zone or halo a third of an inch wide, which would lead one to believe that we live in a luminous fluid, which has enabled us to obtain a photographic print of itself and of the fingers, as if under the influence of light. Dr. Luys has tried the same experiment, but without any results, on patients whose hands were paralyzed, benumbed or insensible to touch. No image appeared on the plate.

W. Toritch & Co., of New York City, have been advised that an electrical exhibition is being planned by the Russian Electro-Technical Society, to take place in St. Petersburg the early part of 1899. Everything pertaining to electricity will be admitted. This will give an opportunity to introduce in Russia, they say, a number of American manufactured goods in the electrical line which heretofore were unknown in that market. The exhibition buildings will be put up in the center of the city. In the surrounding canals electric yachts will ply. Different systems of electric railroads, suspended as well as on sleepers, will be built, and also electric elevators and moving platforms. Some of the buildings put up at Nijni Novgorod for exhibition purposes will be taken to St. Petersburg. At the close of the exhibition some of the principal exhibits will be retained to form an electrical museum in St. Petersburg. Several millions of rubles, which will be necessary for the expenses of the exhibition, will be furnished by the Russian government, the city of St. Petersburg, and by the Electro-Technical Society of that city.

A new cable recorder, invented by M. Ader, is described in La Nature of July 24. It consists essentially of a fine wire stretched vertically in a magnetic field created by a strong horizontal electro-magnet, the poles of which surround the wire. The currents from the cable traverse the wire, which moves to the right or left—that is, toward the north or the south pole of the electro-magnet—according to their direction. A shadow of the wire is projected across a slit, behind which a band of photographic paper travels. A black spot thus falls upon the paper, and as the wire moves to the right or left the movements are traced upon the photographic paper by the shadow of the spot, the result being a record similar to that given by the siphon recorder. The paper is developed automatically in three baths contained in a small dark chamber, and the signals are shown in white upon a black ground. As to the speed obtained, 350 letters a minute, that is, about seventy words, have been recorded through the cable between Marseilles and Algiers, and 150 letters per minute have been recorded upon the Brest-New York cable, the transmitter being at St. Pierre-Miquelon and the receiver at Brest.

SELECTED FORMULÆ.

Remedy for Ants.—Many ways of getting rid of ants have been suggested, but few work satisfactorily. The following, however, has stood the test very well. Lay on a plate, accessible to the insects, several slices of raw meat, exposing as great a surface as possible. Let these stand for some hours, and you will find them crowded with ants, as they greatly relish raw meat. Now throw the whole into fire or boiling water. Repeat the same process, if necessary, till you are no longer troubled.—Science en Famille.

Plate Backing.—Plate backing to prevent halation may be prepared from:

Paraffine wax	20	parts.
Olive oil	20	"
Light lampblack	10	"

Let these melt in gentle heat and apply with flat brush. Before development remove with a knife.

In case of emergency a piece of gelatino-chloride paper, printed to redness, and washed free of silver may be used for backing a plate.—Revue Scientifique.

Lead Paper.—To prepare a lead printing paper proceed as follows: Lay some coarse drawing paper (such as contains starch) on an 8 per cent. potassium iodide solution. After a moment take it out and dry. Next, in the dark room lay the paper face downward on an 8 per cent. lead nitrate solution. This sensitizes the paper. Again let dry. The paper is now ready for printing. This process should be carried on till all the detail is out in a grayish color. Then develop in a 10 per cent. ammonium chloride solution. The tones obtained are of a fine blue black.—Revue Scientifique.

Protecting Iron from Rust.—Iron may be protected against rust by the use of potassium bichromate. A concentrated solution of this substance is brushed over the metal, which, when dry, is heated for some two minutes in a furnace or over a coal fire. The heat reduces the chromic acid, and produces the result desired. To test whether the heating has been carried far enough, rinse the iron with water; if the water is colored, the article must be further heated. If the heating is carried on to excess, the article is covered with a fine black coat.

Putz Pomade.—Many formulas have been published for the production of "pomades" for cleaning and polishing metal. It is said that the well known article sold as "putz pomade" consists of Armenian bole, made into a paste with oleic acid and nitro-benzol enough to give the mixture an odor. The term "putz," it may be explained, is a German one for "cleaning."

J. W. Colcord has proposed the following formula for a paste of this kind:

Oxalic acid	1	part.
Peroxide of iron (jewelers' rouge)	15	"
Rottenstone	20	"
Palm oil	60	"
Petrolatum	5	"

Pulverize the acid and the rottenstone and mix thoroughly with the rouge. Sift to remove all grit, then make into a paste with the oil and petrolatum. A little nitro-benzol may be added to scent the mixture.—Drug Circular.

Cement for Leather Belting.—The importance of suitable cement for making joints in leather driving belts has led the Society of Chemical Industry to indorse the following formula: First, equal parts of good hide glue and American isinglass, softened in water for ten hours, then boiled with pure tannin until the whole mass is sticky, the surface of the joints to be roughened and the cement applied hot; second, one kilogramme of finely shredded gutta percha digested over a water bath with 10 kilogrammes of benzol until quite dissolved, when two kilogrammes of linseed oil varnish are stirred in; third, one and a half kilogrammes of finely shredded India rubber are completely dissolved in ten kilogrammes of carbon bisulphide by heating, and while hot one kilogramme of shellac and one of turpentine are added, and the solution heated until the two latter ingredients are also dissolved; fourth, one kilogramme of the best glue is dissolved at a moderate heat in one and a half kilogrammes of water, and thickened to the consistency of sirup. One hundred kilogrammes of thick turpentine and five grains of carbolic acid are carefully stirred in while hot; the mixture to be poured into flat tin pans and allowed to cool, then cut into pieces and dried in the air. The cement is made liquid with a little vinegar and applied to the joint with a brush; this being done, the two ends of the joint are properly placed together and thoroughly pressed between two iron plates heated to a temperature of about 86 deg. Fah.—Exchange.

Mountant for Photographs.—

Gelatine	16	parts.
Glycerine	1	"
Water	32	"
Methylated spirits	12	"

Let the gelatine soak in water till it is well swollen, then dissolve by the application of gentle heat, and, stirring vigorously, pour in the alcohol in a thin stream. Use warm.—Cosmos.

Bronze for Copper.—Dissolve in 200 parts of water:

Copper subacetate	25	parts.
Copper carbonate	25	"
Ammonium chlorhydrate	45	"
Acetic acid	10	"

In this solution boil the article to be bronzed. Use copper vessel (not tinned).—Cosmos.

Remedy for Insomnia.—A simple and harmless remedy against nervous insomnia consists in laying a moist cloth on the neck.—Der Stein der Weisen.

Ashes for Lawns.—Ashes strewn on lawns prevent the growth of moss and promote that of the grass. Soot, which is often thrown away, is an excellent fertilizer, particularly for grass, onions, potatoes, and all kinds of radishes. Both ashes and soot have the property of keeping away sand fleas and little snails. An excellent fertilizer is obtained by mixing nine parts of soot with one of salt.—Der Stein der Weisen.

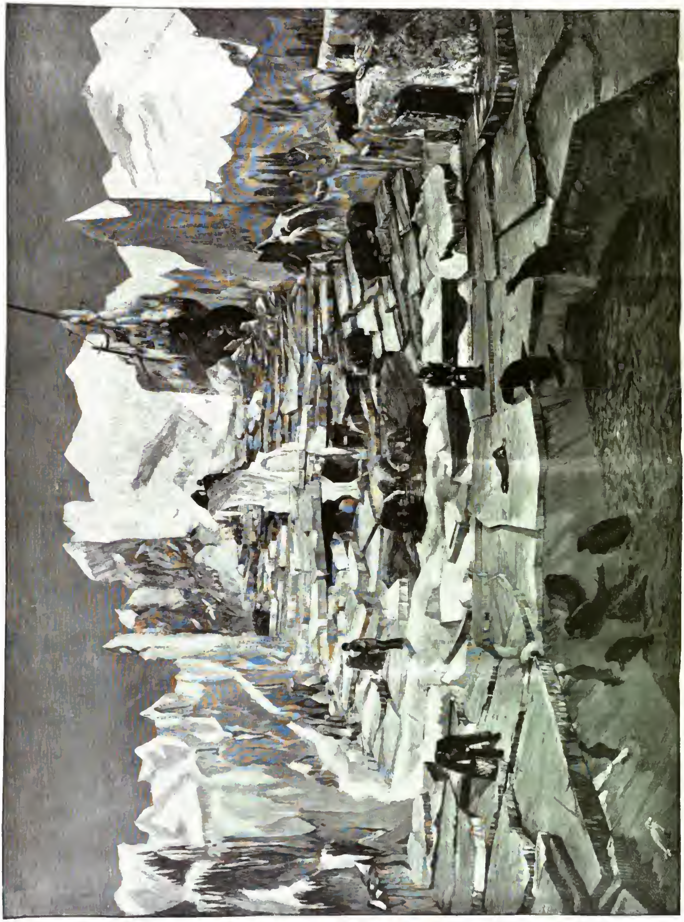
HAGENBECK'S PANORAMA OF A NORTHERN SEA.

THE vivid interest in the regions far north, which was so remarkable in days gone by, has recently been stirred anew by the successful efforts of Nansen and Andrée's daring enterprise. In anxious suspense the whole world awaits the time when news from the aeronaut will be received, and our imagination figures up before our eyes a picture of desolate, snow-covered plains, beset with huge and shapeless blocks of ice, and animated with fearful polar bears and inoffensive seals, a scene from the land where so many explorers have succumbed in battle with a great and dreadful foe.

But a more concrete representation than these fancies of our minds has been set before the interested European. Transplanted, as if by a magician's wand, from regions of perpetual snow into our temperate zone, a scene of Arctic life is laid amid the busy life of the great Hanseatic town of Hamburg.

Charles Hagenbeck, the well known dealer in wild animals, has, by the aid of painter and sculptor, constructed an artistic panorama of a northern sea, and has added a novel charm to it by animating the scene with live beasts.

On entering the panorama the visitor is ushered into an ice grotto, from which he looks on the Arctic landscape. On his right and left great icebergs of extravagant shape rise from the ground. Their forms bound the horizon on either side. In the foreground the sea is covered with blocks of ice, which, in some places, have glided on one another, forming heaps, and in one



PANORAMA OF ARCTIC LIFE AND SCENERY.

spot have left an opening where the seals, cormorants and sea gulls are able to enjoy a fresh bath. In the rear the floating ice has been crushed together more strongly, towering up high, and holding up an ice-covered ship. The background is formed by the ice and snow covered coast of an Arctic island.

Quite a number of bears—about a dozen—are free in this panorama. Apparently there is no barrier separating them from the lookers-on. No grating divides their domain from us, so that we imagine that they might, if they pleased, pay us an unwelcome visit. But our safety has been sufficiently provided for. The bears are inclosed in a large den, the sides of which are found in the iceberg walls of the panorama, while the front is secured, unlike the front of the dens in the zoological gardens, by a deep, dry ditch, with smooth sides, which stretches across the landscape, dividing foreground from background. This ditch is hidden from the view of the visitors by a clever arrangement of the scenery, and is so made that no bear would attempt to slide down one wall and climb up the other.

With perfect composure we may, then, stay to watch the feeding of the animal inhabitants. An Eskimo, clothed in sealskin, appears in the foreground. As soon as the seals notice that he is carrying fishes, they raise their hoarse barking voices, sea gulls and cormorants join with their croaking cries; everything comes into motion. All sorts of salt water fish are distributed as food—herrings, shellfish and others.

Birds and mammals alike have a healthy appetite. Not only do the seals swallow their food whole, but the sea gulls, too, take very large bites; and even the cormorants swallow whole shellfish without much ado.

Then the polar bears, too, are visited by an Eskimo. With a great whip he drives the great beasts before him like a herd of sheep. One bear, who turns back, he pats on the head, another he strokes on the back. Evidently, he is not afraid of the bears, and they are not afraid of him. They take their food from his hand and catch in their mouths the pieces thrown to them. They are splendidly trained, and obey their keeper on a word or even a sign—a fact which surprises us when we think of the vicious character of this particular species of bears.

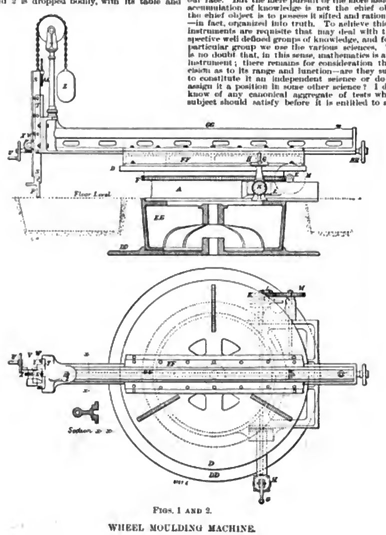
In the evening the sea is brilliantly illuminated by concealed electric arc lamps, while the icebergs in the back are set aglow by an imitation of polar light.

Last summer this panorama formed one of the attractions of the Berlin Exhibition. At the present time it is on view at Hamburg, as we mentioned above.

Our illustration is from Illustrite Zeitung.

MACHINE MOULDED WHEELS.

THE accompanying illustrations are those of the machines of Messrs. Buckley & Taylor, of Oldham. D D is a plate permanently sunk in the floor. E E is a foundation ring or pan which fits within, and which is tapered to facilitate its removal when the floor happens to be wanted for other work. Into E E the base A in Figs. 1 and 2 is dropped bodily, with its table and



FIGS. 1 AND 2.

WHEEL MOULDING MACHINE.

wormwheel, fitting by means of a central pin into the boss in E E.

Upon the table is bolted the seating and guide, with loose strips, in which the radial arm, G G, is slid by means of a screw and handwheel, H H, seen at the right hand. The great length of the slide and of the adjustable strips removes all objections on the score of tipping, which becomes a source of serious trouble when moulding wheels of large diameter. The mechanism for the vertical movement of the block can be a permanent fixture on the end of the arm, or it can be detached from the jib of the table machine and bolted to the radial arm.—Engineering.

THE BRITISH ASSOCIATION—ADDRESS IN MATHEMATICS AND PHYSICS.

THE address in Section A was delivered by Prof. A. R. Forsyth, M.A., D.Sc., F.R.S., who, in the course of his remarks, referred to the relations which pure mathematics have with other branches of science, and appealed for more attention to be paid to them. It is not enough for my purpose, he said, to be told that the British Association includes all science in its scope, and consequently includes pure mathematics. A statement thus made might be framed in a spirit of mere sufferance; what I wish to secure is a recognition of the subject as one which, being full of life and overflowing with a power of growth, is worthy of the most absorbing devotion.

It will readily be conceded for the present purpose that knowledge is good in and by itself, and that the pursuit of pure knowledge is an occupation worthy of the greatest efforts which the human intellect can make. A refusal to concede so much would, in effect, be a condemnation of one of the cherished ideals of our race. But the mere pursuit or the more assiduous accumulation of knowledge is not the chief object; the chief object is to possess it sifted and rationalized—in fact, organized into truth. To achieve this end, instruments are requisite that may deal with the respective well defined groups of knowledge, and for one particular group we use the various sciences. There is no doubt that, in this sense, mathematics is a great instrument; there remains for consideration the decision as to its range and function—are they such as to constitute it an independent science or do they assign it a position in some other science? I do not know of any canonical aggregate of tests which a subject should satisfy before it is entitled to a separate establishment; but in the absence of a recognized aggregate, some important tests can be assigned which are necessary, and may, perhaps, be sufficient. A subject must be concerned with a range of ideas forming a class distinct from all other classes; it must deal with them in such a way that new ideas of the same kind can be associated and assimilated; and it

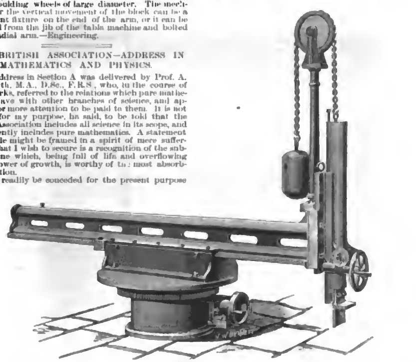


FIG. 3.

should derive a growing vigor from a growing increase of its range.

For its progress, it must possess methods as varied as its range, acquiring and constructing new processes in its growth; and new methods on any grand scale should supersede the older ones, so that increase of ideas and introduction of new principles should lead both to simplification and to increase of working power within the subject. As a sign of its vitality, it must ever be adding to knowledge and producing new results, even though within its own range it propound some questions that have no answer and other questions that for a time defy solution; and results already achieved should be an intrinsic stimulus to further development in the extension of knowledge. Lastly, at least among this list, let me quote Sylvester's words: "It must unceasingly call forth the faculties of observation and comparison; one of its principal methods must be induction; it must have frequent recourse to experimental trial and verification, and it must afford a boundless scope for the highest efforts of imagination and invention." I do not add as a test that it must immediately be capable of practical application to something outside of its own range, though of course its processes may be also transferable to other subjects, or, in part, derivable from them. All these tests are satisfied by pure mathematics; it can be claimed without hesitation or exaggeration that they are satisfied with ample generosity. A complete proof of this declaration would force me to trespass long upon your time, and so I propose to illustrate it by references to only two or three branches. First, I would refer to the general theory of invariants and covariants. The fundamental object of that theory is the investigation and the classification of all dependent functions which conserve their form unaltered in spite of certain general transformations effected in the functions upon which they depend.

Originally it began as the observation of a mere analytical property of a particular expression, interesting enough in itself, but absolutely isolated. This then suggested the inverse question: What is the general law of existence of such functions if they exist as more than mere casual and isolated occurrences? and how can they all be determined? The answer to these questions led to the construction of the algebraical theory of invariants for linear transformations, and subsequently to the establishment of covariantive forms in all their classes. Next came the question of determining what is practically the range of their existence—that is, is there a complete finite system of such functions in each particular case? and, if there is, how is it composed, when in a form that ought to admit of no further reduction? These questions, indeed, are not yet fully answered. While all this development of the theory of invariants was made upon these lines, without thought of application to other subjects, it was soon clear that it would modify them greatly. It has invaded the domain of geometry, and has almost recreated the analytical theory; but it has done more than this, for the investigations of Cayley have required a full reconsideration of the very foundations of geometry.

It has exercised a profound influence upon the theory of algebraical equations; it has made its way into the theory of differential equations; and the generalization of its ideas is opening out new regions of the most advanced and profound functional analysis. And so far from its course being completed, its questions fully answered, or its interest extinct, there is no reason to suppose that a term can be assigned to its growth and its influence.

As one reference has already been made to the theory

of functions of a complex variable, in regard to some of the ways in which it is providing new methods in applied mathematics, I shall deal with it quite briefly now. The theory was, in effect, founded by Cauchy; but, outside his own investigations, it at first made slow and hesitating progress. At the present day, its fundamental ideas may be said almost to govern most departments of the analysis of continuous quantity. On many of them it has shed a completely new light; it has educed relations between them before unknown. It may be doubted whether any subject is at the present day so richly endowed with variety of method and fertility of resource; its activity is prodigious, and no less remarkable than its activity is its freshness. All this development and increase of knowledge are due to the fact that we face at once the difficulty which even the schoolboy meets in dealing with quadratic equations, when he obtains "impossible" roots; instead of taking the wily x as our subject of operation, we take the still wilier $x + y \sqrt{-1}$ for that purpose, and the result is a transfiguration of analysis. In passing, let me mention one other contribution which this theory has made to knowledge lying somewhat outside our track.

During the rigorous revision to which the foundations of the theory have been subjected in its reestablishment by Weierstrass, new ideas as regards number and continuity have been introduced. With him, and with others influenced by him, there has thence sprung a new theory of higher arithmetic; and with its growth, much has concurrently been effected in the elucidation of the general notions of number and quantity. I have already pointed out that the foundations of geometry have had to be reconsidered on account of results finding their origin in the theory of invariants and covariants. It thus appears to be the fact that, as with Plato, or Descartes, or Leibnitz, or Kant, the activity of pure mathematics is again lending some assistance to the better comprehension of those notions of time, space, number, quantity, which underlie a philosophical conception of the universe. The theory of groups furnishes another illustration in the same direction. It was begun as a theory to develop the general laws that govern operations of substitution and transformation of elements in expressions that involve a number of quantities; it soon revolutionized the theory of equations. Wider ideas successfully introduced have led to successive extensions of the original foundation, and now it deals with groups of operations of all kinds, finite and infinite, discrete and continuous, with far reaching and fruitful applications over practically the whole of our domain. So one subject after another might be considered, all leading to the same conclusion.

I might cite the theory of numbers, which has attracted so many of the keenest intellects among men, and has grown to be one of the most beautiful and wonderful theories among the many in the wide range of pure mathematics; or, without entering upon the question whether geometry is a pure or an applied science, I might review its growth alike in its projective, its descriptive, its analytical, and its numerative divisions, or I might trace the influence of the idea of continuity in binding together subjects so diverse as arithmetic, geometry, and functionality. What has been said already may, however, suffice to give some slight indication of the vast and ever widening extent of pure mathematics. No less than in any other science, knowledge gathers force as it grows, and each new step once attained becomes the starting point for steady advance in further exploration. Mathematics is one of the oldest of the sciences; it is also one of the most active, for its strength is the vigor of perpetual youth.

CUINAT'S ACETYLENE GAS GENERATOR.

In the acetylene gas generators in which the water falls upon the calcium carbide there are several serious difficulties to be avoided, the greatest of which is overproduction. When the carbide is fresh, the disengagement of the gas is proportional to the quantity of water introduced, but, inasmuch as the liquid first saturates the lime that envelops the carbide before coming into contact with the latter, the proportion of the discharge is no longer theoretical. At the stoppage of the flow, the excess of water thus introduced causes the subsequent decomposition of the carbide, since, in cooling, the lime liberates a portion of the water that it has absorbed. It is therefore either necessary to arrest the normal operation of the generator before suspending that of the consumption apparatus or to allow the gas produced in excess to escape into the air with every precaution possible. There is to be feared, too, an elevation of the temperature resulting from the reaction of small quantities of water in a relatively large mass of carbide.

An endeavor has been made to overcome such difficulties in many ways. Certain inventors throw the carbide into the water, while others introduce it at the bottom of the carbide receptacle, where it progressively ascends.

It is to this category that belongs the generator devised by Mr. Cuinat, and represented herewith. Its arrangements are such that the production of acetylene is absolutely independent of the greater or less regularity with which the friable mass of the residue settles. Were it otherwise, the level of the water might undergo abrupt changes capable of causing an irregular production of gas.

Two distinct receptacles contain the water and the carbide. According to the size of the apparatus, the water reservoir either surmounts the gasometer (Fig. 1) or the carbide receptacle, with which it in both cases is connected by a conduit provided with an ordinary cock at the top and an automatic one at the bottom.

The carbide of calcium is not stored up in a mass, but is distributed in layers of slight thickness. Each of these latter is contained in a circular basket consisting of a solid iron plate disk riveted to a ring about 22 mm. in height, the periphery of which is provided with numerous apertures. These baskets are superposed in their common receptacle, which is capable of holding twenty of them connected in groups of four by means of a couple of pins. These baskets are of variable dimensions, which are so determined that the carbide of each of them shall disengage a volume of acetylene just sufficient to fill the holder of the gasometer. In the type capable of supplying 48 burners consuming 30 liters an hour for five hours, each contains 750 grammes of carbide. After they have been charged, they are piled up in the generator, which is then closed by means of a cover held either by a bridge and bolt (Fig. 1) or by a series of thumb nuts that can be rapidly manœuvred (Figs. 2 and 3).

From the top of this receptacle starts a large conduit that connects with a tubulure fixed to the bottom

FIG. 1.—CUINAT'S ACETYLENE GAS GENERATOR.

of the tank of the gasometer and prolonged by an ascending conduit whose upper part is curved so as to plunge to a slight depth into the water of the tank.

When the apparatus is set in operation, the holder of the generator occupies its lowest position. A tappet fixed to its dome then rests upon the jointed lever of the automatic cock established at the foot of the water pipe and holds it open. As soon as the upper cock is opened the apparatus begins to work.

The water entering the carbide receptacle deluges the contents of the first basket. A chemical reaction at once occurs and the acetylene becomes disengaged and flows to the gasometer, whose holder rises progressively and, at the same time, liberates the lever of the automatic cock, which, under the action of a spring established around the key, gradually closes. The complete shut-off occurs at the moment at which the holder reaches such a position that the subsequent disengagement of acetylene suffices to complete the filling of it at a normal pressure. In this way, there enters each time into the generator properly so called only the quantity of water necessary to cover a single basket, the contents of which correspond to one filling of the holder. All the baskets of the upper rows remain untouched. In truth, the aqueous vapor disengaged is capable of causing a beginning of decomposition of the carbide that it holds in reserve; but the arrangements provided limit the action of this vapor in a large measure. In fact, as the carbide is compressed between solid disks the vapor can hardly come into contact with it except through the apertures in the side of the basket.

Experience has shown that such precautions are very efficacious. In fact, all overproduction and, consequently, all danger of explosion are prevented. We have found on several occasions that gas generators of this system can be arrested in their operation at any moment without giving rise to an appreciable elevation of temperature.

By reason of its avidity for water, calcium carbide constitutes the desiccative par excellence of acetylene; so that the outlet pipe, which is a little above the maximum level that the water in the gasometer tank assumes, ends at a large vertical cylinder filled with carbide that is traversed by the gas before it flows to the apparatus where it is to be used.

In measure as the acetylene disappears from the holder, the latter descends. Its tappet soon meets the lever of the automatic cock and causes it to open progressively. A definite quantity of water enters anew and covers the carbide of the second basket, and the acetylene produced fills the holder again. Upon the gas generator (Fig. 1) there is a water level indicator by means of which the row of the last basket exhausted, and, consequently, the charge of carbide remaining disposable may at once be recognized.

The funnel shaped bottom of this receptacle facilitates the expulsion of the residue through a central mud cock. If one has two sets of baskets at his disposal, the recharging of the gas generator may be done very rapidly.—Revue Industrielle.

DR. MOUNT BLEYER'S TREATMENT FOR CONSUMPTION BY ELECTRICITY.

On the application of the principles underlying these experiments in the sterilization of lung tissue in tuberculosis.

The primary action of the galvanic current—It increases the amount of ozone in the blood, as shown by chemical test of the blood in the arteries—With my theory of animal electricity.*

By J. Mount Bleyer, M.D., F.R.A.M.S., LL.D., New York City.

Schönbein, in drawing his conclusions regarding the nature of ozone, assumed that oxygen was capable of three distinct conditions, viz., ozone electro-negative, antozone electro-positive, and neutral oxygen, which, as its name indicates, had no polar distinction, but could be polarized and depolarized at will.

Of these three so-called forms of oxygen, the investigations of the observers since the day of the great Basle chemist have much changed our views. To-day we admit the existence of only two forms of oxygen—ozone and neutral oxygen; and for the sake of elucidation, I give you the graphic construction of the molecule as I believe it to be:

$$\bar{O} \quad \overset{+}{O} \quad \bar{O} = \text{ozone.}$$

$$\bar{O} \quad \overset{+}{O} = \text{neutral oxygen.}$$

Assuming, as he and the after-coming observers did,

* Read before the Twelfth International Medical Congress, Moscow, Russia, August 19, 1897. By special invitation.

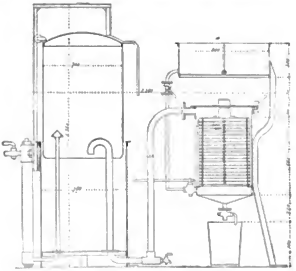

FIG. 2.—VERTICAL SECTION.

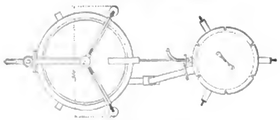

FIG. 3.—PLAN.

that oxygen in its free state was neutral—and it so proved to be—he reasoned—and it is within the pale of all researches, even up to our own time—that as soon, or rather, as I have found it, just before, this oxygen enters into combination with either organic or inorganic substances, in the presence of moisture it becomes polarized.

Carrying these conclusions into the field of physiological chemistry, he became convinced that the corpuscles, like phosphorus, were possessed of the power of polarizing the oxygen in the lungs, and further of splitting up the molecules and rearranging them in the form of ozone. His idea was that ozone existed in the blood, that it was the vital oxidizing agent by means of which the recuperative changes in the tissues were brought about; yet the years of careful work he devoted to searching, failed him in finding the slightest trace of ozone in the blood.

In his later years he became equally emphatic in his assertion that the resolution of ozone, its oxidation, was so rapid that the blood and the moistened tissues surrounding the capillaries, where the real respiration is accomplished, it would be next nigh impossible to chemically detect the presence of ozone by the most delicate test. He even went so far as to doubt its existence in the blood, that is to say, he believed that it was ushered into existence, and was used up in performing its function so quickly that it was not possible to chemically isolate it; that in the blood of the capillaries—presumably the radicals, although he does not so put it—where the pressure conditions are such as to allow of the free interchange of the gases of the blood with the tissue elements, ozone no longer existed.

Like many other great minds, Schönbein was right in many of his claims, but in many other of his theories he allowed himself to fall into error; for, in justice to those who came after him, to study this question of the physiological significance of ozone, and with no discredit to his greatness, Schönbein left much to be cleared up and explained. The ever changing and improving chemical facilities and knowledge made this task far more easy. With the advantages afforded by the chemistry of his day, Schönbein accomplished an herculean task. That famous physiologist, His, who had grown up in the shadows of Schönbein's laboratory and influence, also failed to discover the existence of ozone in the blood.

At the very time His was engaged in his futile efforts, Alexander Schmitt was at work upon the same question—ozone in the blood.

I need not rehearse the details of Schmitt's methods. Suffice it to say his experiments were elaborate and carefully made, and showed beyond doubt that ozone existed in the blood, but the quantity apparently was very small.

Not long afterward, Kühne, improving on Schmitt's tests, proved that ozone existed in the blood in readily appreciable quantity, and the question was forever settled in the affirmative.*

Kühne concluded, and his deductions were not far from approximating the truth, that the red corpuscles greedily absorb ozone under the natural formation of carbonic acid and decompose water as free oxygen is liberated.

Any experiments on the blood with the galvanic current are in a line with those of Kühne and Schmitt, only a short step in advance of those observers, a mere completion of their unfinished tasks. Whatever value the results I have obtained may have, there can be no doubt that the galvanic current applied to the living body, whatever else its action may be, increases the amount of ozone both in the corpuscle and the plasma.

Before entering into a rehearsal of the details of my experiments, let me briefly touch upon the physiology of the blood, the function of its gases, for here it was that I suspected the seat of first physiological action of the galvanic current, and here, too, I was led to trace to its source animal electricity, and observe its function, as I suppose it, in the human economy.

THE BLOOD—ITS GASES AND SOLIDS.

The gases in the blood, the carbonic acid, the nitrogen and the oxygen, which interests us in particular, need not be gone into at length.

The oxygen in the blood exists in two forms—first, that which is held in solution by the plasma, and second, that which enters into combination with the constituent elements of the corpuscle.

The first variety commands our attention for the reason that to all appearances the galvanic current first acts upon this freely dissolved oxygen, and which naturally, therefore, first undergoes the transforming change from O_2 into O_3.

With a single exception, that of defibrinated blood, the blood obeys Dalton's well known law of the absorption of gases by liquids. In vacuum 100 volumes of blood give up a trifle over 73 volumes of gas, of which in arterial blood 20 volumes upon analysis consist of oxygen, while in venous blood the volumes are reduced to between 8 and 10.

The plasma simply holds the oxygen in solution, while the hemoglobin, which by actual weight makes up 90 per cent. of the dried corpuscle, enters into partial combination with the oxygen, although I have observed, and the observations are in keeping with those of other observers, that the oxygen in the hemoglobin is in such a loosely combined state that it readily solves its bonds of union, and under the slightest provocation goes over to the other elements for which it has affinity as soon as the pressure conditions of the plasma are changed so as to permit of a loosening of its bonds.

Plasma, or to be more accurate, fresh serum will upon exposure to the air absorb no more gas than ordinary water under similar conditions, some three volumes; defibrinated or whipped blood, however, contrary to what might be expected, takes up considerably more. This will suffice for the behavior of the gases of the blood; now a word about its solid constituents.

In general, in the plasma there are serum, albumen, globulin and crystallizable, fatty and nitrogenous matter, which, as I shall endeavor to show, are rendered more diffusible by this very transformation of oxygen into ozone, either caused by the polarizing action of the existing animal electricity of the body, or may be rendered more so by the action of the galvanic current.

In the larger vessels, for example, the carotid artery, which I have chosen as the seat of my experimentation, not only because it is accessible and convenient, but rather because it is a direct branch of the aorta, where both the plasma and corpuscles are equipped with all the oxygen they can carry, the blood is charged to its full capacity with these elements, which it is commissioned to give up to, and upon which the tissues depend, particularly oxygen.

All physiologists agree that in these large vessels carrying arterial blood the hemoglobin in the corpuscle is in the form of oxyhemoglobin, which signifies simply that the hemoglobin has entered into partial combination with as much oxygen as it can hold, and that it is ready to transfer this oxygen to the tissues as soon as the oxygen of the plasma has become exhausted and the pressure conditions become so reduced as to permit the giving up of the gas.

This occurs in the capillaries. Until these are reached the pressure of the oxygen in the plasma restrains the hemoglobin from giving its oxygen. Here in the liquid moistening the fibrillæ of muscle that surround the terminal capillaries, where the transfer of oxygen in reality begins, the tension of the oxygen is almost nil, since the tissue elements are steadily taking up the gas from the lymph surrounding them, and the plasma continues to give up oxygen through the walls of the capillaries, until the tension falls too low for it to longer do so; then it is that a portion of the oxygen of the hemoglobin is freed and is dissolved in the plasma to take the place of that oxygen which it has given up and which, in turn, has passed out into the lymph on the other side of the capillary wall. This interchange continues until the pressure of the oxygen in the lymph equals that of the oxygen in the plasma, by which time the venous system of capillaries of the return circulation has been reached.

One of the strong indications of the action of the galvanic current on the blood is the probability that it facilitates this transfer of oxygen to the tissues in active form, both chemically and physically. By rearranging the atoms of some of the molecules of oxygen in the plasma the volume of the oxygen held in solution is reduced, and the oxygen of the hemoglobin is at once transferred to the plasma instead of being doled out, as it were, to suit the constantly varying pressure changes that go on as the blood completes its circulatory round. This being the case, the transforming process is undoubtedly ushered into existence through the polarizing property of the animal electricity, of which I shall speak further on.

How far chemical change is brought about upon the diffusible solids of the blood by the generation and presence of such an increased amount of ozone I am unable to make precise answer, and I leave it to the thoughtful investigation of those observers who may take interest in my work and who are blessed with a more acute knowledge of physiological chemistry and a more completely equipped laboratory than it is my good fortune to possess. To my mind there seems little question of the occurrence of just such a change as I have described. My analyses thus far have remained within the sphere of quality; it remains for others to continue in the more exact line of quantity. Reasoning by analogy, the galvanic current acts precisely upon the oxygen in solution in the plasma as it did in the jar filled with it, through which Schönbein passed the current and observed its transformation into ozone.

There is but one possible action of the ozone in the blood. It must hurry on the transfer of the oxygen to the tissues; call into existence the oxidation of those constructive elements which the tissues require for their revivification. Doubtless these changes are more extensive than I have been able to determine exactly.

OTHER FACTORS TO BE CONSIDERED.

The experiments of Gay-Lussac should teach us a valuable physiological lesson. From his laboratory we feel that we can carry them over to that storehouse of chemical energy, the human body, and observe changes corresponding to those he observed in his jars filled with gases possessed of great affinity for each other, which, however, remained quiescent and inactive until he provided them with the stimulus of a galvanic current, which, as it passed through the gases, spurred into action, or awakened, as it were their slumbering affinities, polarized their molecules, and ushered into life the new something, the result of the three great potent factors, polarization, chemical action and affinity. I have tried to impress upon you the importance of these three conditions, for upon them depend all the chemico-physiological changes, in short, all changes that go on within the human body.

I have observed them time and again in the course of my experimenting and have subjected them singly and together to the most rigorous test of verification.

My observations point to the one conclusion, and that is that chemical action, the feeder of life, cannot go on unless there is present an electrical force, an energy that can polarize the molecules of the combining elements, and prepare them for combining action. Affinity, catalysis, the phenomena of contact, in themselves are impotent without that ever preceding factor—molecular polarization.

It is the metabolism, the anabolism, the katabolism, the all, and more were it possible, of that cardinal nourisher of tissues, that feeder of life, the Blood.

Animal electricity and the important part it plays, I will reserve for a later chapter and pass over to general details of my experiments upon the blood of the living animal in its normal state and under the stimulus of the galvanic current.

(To be continued.)

* Kühne and Scholz, Virchow's Archiven, 1865.

THE INFLUENCE OF LIGHT ON THE SKIN.

IN the July number of the British Journal of Dermatology Dr. Robert L. Bowles states that he has for many years been engaged in investigating the effects of sunlight on the human body, and especially the penetrating effects of rays reflected from snow and other surfaces. Professor Roentgen, he says, finds that certain rays generated or excited by electrical action penetrate most of the human tissues and other substances, and are stopped by substances of a different nature. The author, on the other hand, has demonstrated that reflected luminous or photochemical rays also penetrate the human skin into the deeper tissues beneath and produce within them great and important changes. He gives the following summary of facts and conclusions of various phenomena observed by him from time to time:

1. That heat qua heat is not the cause of sunburn.

2. That there is strong reason for believing that sunburn is caused by the violet rays or ultra-violet rays of light reflected from snow, and that it is not necessarily of the same quality as that which is incident.

3. That Captain Abney finds that the violet or ultra violet rays are very strong at high altitudes, and believes that altitude has much to do with sunburn.

4. That altitude alone does not explain sunburn; for one may be unburned on rocks, say at ten thousand feet, and yet become immediately affected on descending to a glacier three or four thousand feet lower.

5. That sunburn and snow blindness arise from similar causes, and that sunstroke and sun fever may be associated with the effects of penetrating light rays.

6. That rays from the electric light produce much the same results as sun rays reflected from snow.

7. That the bronzing of the skin and the browning of the wooden châlets are probably produced by rays reflected from snow.

8. That various pigments, but chiefly those containing red and yellow, stop or alter reflected rays and prevent the physiological and pathological changes usually due to them.

9. That freckles, which are but the milder effects of luminous or chemical rays, stop the penetration of those rays though the skin.

10. That the sometimes very serious inflammatory changes in sunburn and in what Mr. Hutchinson designates "summer eruptions" are due to the penetration of reflected luminous or photo-chemical rays through the skin to the deeper tissues beneath.

11. That photography often demonstrates the existence of freckles and, report says, various eruptions deep in the skin which are perfectly invisible to the naked eye, showing that the luminous or photo-chemical rays are stopped or altered by them, and not reflected back, as no change is produced on the negative—an effect which suggests that these photogenic rays have penetrating powers as yet unknown.

12. That the wood of Swiss châlets is burned perfectly black (carbonized) on its surface by rays reflected from snow, which rays in time penetrate deep into the substance of the wood and change it to a dark-brown color.

13. That the first effect of snow rays on a new châlet is shown by its action on the resin of the wood, which "sweats out" and leads more easily to the charring of the woody fiber itself and the subsequent changes in the deeper parts.

14. That Captain Maude, R.E., has shown from his own personal experiences and from experiments on many friends, that solar rays in India produced sun fever of a very serious kind, which was entirely prevented by the wearing of an orange lining to all his clothes and inside his hat. These experiments demonstrate the penetrating power of light rays through clothes unprotected by color, and their important influence on health. In relation to this, the author has shown that a lady wearing a linen blouse with red and white stripes was strongly marked with red and white stripes on her shoulders, but the red line on her skin corresponded with the white lines of the linen—that is, the red stripes had completely stopped all rays from affecting the skin beneath them.

15. That the author has often shown that rays reflected from certain surfaces—such as water, gold and silver lace, white walls, white veils, certain clouds and mists—act physiologically in a peculiar manner and quite differently to direct light, and that some physical change hitherto unexplained must take place in light during or after reflection.

16. That in relation with the foregoing are those marvelous changes in the vegetable kingdom connected with the formation of chlorophyl and the deposition of starch.

From these and many other observations Dr. Bowles says that he cannot help feeling that Roentgen rays may be modifications only of ordinary light, and that their further elucidation must go hand in hand with a further inquiry into the profound changes caused by reflection to which he has above referred. It need not necessarily be assumed, he thinks, that what we call darkness implies an absence of all the forms of light.

In August, 1896, the author, assisted by Mr. Travers, undertook some experiments to discover the cause of the radiant energy from snow being so much more irritating to the eyes and skin than direct energy from the sun, as follows:

1. To show the relative values of sunlight and snow-light in freeing iodine from its combination with hydrogen.

2. To test the relative effects of sun on xxx Pagel's plates, inclosed in cases made of aluminum and cardboard, in producing pictures like those of Roentgen.

These exposures, says Dr. Bowles, were effected on snow at an elevation of eight thousand and forty feet, near the hut of the Ober Aletch Glacier, on three consecutive days. The weather was bad and uncertain, but there was some sunlight, and some interesting and definite results were obtained.

Bottles containing equivalent proportions of a sulphuric acid solution and potassium iodide were fixed in cases and exposed simultaneously to the sun and snow; some bottles were coated with pigments, others with cloth of various colors, but each case contained also some of the solution in an uncovered bottle as a control experiment.

The results were expressed in iodine equivalents, and they appear, he says, as Mr. Travers expresses it, "to indicate that the actinic value of the reflected light from snow is somewhere about 0·7 to 0·8 of the value of the direct rays of the sun."

The X ray plate exposed to the sun displayed skiagraphs of a piece of tin, whereas on the plate exposed to the snow no change could be detected; but as there are reasons for the possibility of this plate having been spoiled, this experiment was not conclusive. The author quotes Mr. Travers, in his remarks on the experiments, as follows:

"In dealing with the published accounts of the cases of sunburn and dermatitis produced by the so-called X rays, it is not at all certain that the injury done

to the hands and arms of the operators was due to the rays which are capable of penetrating aluminum sheets, etc. We know that the radiations from a Crookes tube include rays which come within the visible portion of the spectrum, and it is to these rays that we may attribute the power of producing sunburn.

"Further, while it takes a very long time to produce sunburn in the neighborhood of a tube which will fog a photographic plate, contained in a dark slide, in a few seconds light reflected from the snow will sunburn in a very short time, but will not fog a plate in a dark slide.

"In a paper which appeared either in the Lancet or British Medical Journal a few weeks ago, it was shown that the effect produced by certain kinds of light—e. g., light from incandescent gas or arc lamps—produced injurious effects. The injury could not be attributed to the presence of a greater intensity of ultra-violet or violet light than was present in sunlight, but was due to the absence of 'red' radiation.

"In the reflected light from snow the heat rays are nearly entirely absent. The violet (chemical) rays would be present with almost the same intensity as in the direct sunlight.

"Considering the lack of evidence in favor of the X rays pure and simple being a cause of dermatitis similar to sunburn, it is worth while reviewing the facts in support of the theory that the true cause is to be found in the violet or chemical rays, or in the increase of intensity of the violet rays with regard to the intensity of the red rays.

"I think that the facts cited in your paper (British Medical Journal, March 7, 1896) furnish sufficient support."

Here, continues the author, from an entirely physical point of view, Mr. Travers, like others, arrives at conclusions similar to his own, namely, that the vital changes on the skin are due to the chemical rays, and apparently to those rays alone, and that the rays issuing from a Crookes tube are not an entirely new form of energy distinct and separate from light, but contain a proportion of luminous and chemical rays, and that light, as such, as well as the divisions into which it can be split up, may penetrate wood, clothing and the human tissues.

Dr. Bowles refers to Dr. Unna, who, in 1885, dealt very fully with the subject of pigmentary changes in the cutis, and suggested that they depended on the effects of the chemical rays, and that curcuma and colors acting on the light rays would prevent changes taking place. He refers also to an excellent paper by a Dr. Hammer of Stuttgart entitled "The Influence of Light on the Skin," in which the author deals with the subject first biologically; for example, the action of light on worms and other sightless creatures influenced by light through the skin. On the physical side he quotes the experiments of Terrier, Malakoff, and Widmark. From the beginning to the end, Dr. Bowles says, he found Dr. Hammer's work entirely corroborative of his own, but thinks that Dr. Hammer is not sufficiently impressed with the important fact that reflected light burns much more rapidly than direct.—New York Medical Journal.

THE ELECTRIC LIGHT IN RHEUMATISM.

Dr. Kozlovski, a St. Petersburg physician, publishes in the Vrach an account of his method of treatment of rheumatism and neuralgia by means of exposure to the electric arc, says the English Electrical Engineer. He was induced to make these observations by the statement of Dr. Ewald, who is medical officer to some large ironworks, that he had noticed that since the introduction of the system of electric welding there had been a notable diminution in the number of cases of rheumatism, neuralgia, migraine, and other nervous diseases among the workmen, which he attributed to the beneficial effect of the electric light. In order to bring this therapeutic agent within the reach of ordinary patients, Dr. Kozlovski has fitted up consulting rooms with a suitable plant for producing the electric arc, which consists of a 6 horse power oil engine, a dynamo, 35 Tudor accumulators, a rheostat, amperemeter, and electric arc lamp with reflector. With these he obtains an E.M.F. of 50 or 60 volts and a current of from 250 to 300 amperes. The patient is placed at a distance of 1½ meters from the light and protected by blue spectacles and also by a screen of cardboard in which an aperture is cut to allow the light to fall on the affected region of the body. To this it is exposed for from three-quarters of a minute to two minutes. At the time the patient feels a slight sensation of heat, though the temperature is never raised more than 4° F. where the light falls on the skin, but nothing more until six or eight hours afterward, when itching and tingling are felt and the skin becomes reddened. Some 48 hours later desquamation occurs, which lasts for two or three days. In the course of three months Dr. Kozlovski has treated 38 patients, varying in age from 13 to 70 years, by the electric light. There were eight cases of sciatica, all of which recovered; four of neuritis (locality not stated), two of which recovered; 18 of chronic rheumatism, 14 of which recovered; and three of lumbago, all of which recovered. In most cases three or four sittings produced an amelioration of the pain. They were continued at intervals of three or four days, according to the amount of cutaneous irritation, but the total number of sittings never exceeded a dozen. This extract we culled from the Lancet, and are glad to note that as the electric welder was developed by exaggerating the faults of a transformer, so the ill effect of the rays from the welder has some compensating good properties. We suppose that shortly the electric lighting station will be dispensing two minute doses of strong arc light to rheumatic consumers.

It appears that the trade of Marseilles has been decreasing for some time past. In 1891 the total import and export business of that large Mediterranean port amounted to 2,045,800,000 francs. In the following year it decreased 198,000,000 francs, and in 1893 the falling off against 1891 was nearly 280,000,000 francs. In 1894 and in 1895 the decrease was rather less marked, but in 1896 it amounted to no less than 282,000,000 francs. The Marseilles trade has accordingly lost, on an average, 250,000,000 to 300,000,000 francs per annum, or one milliard—200,000,000 francs during the six years from 1891 to 1896.

STRINGING A TELEGRAPH LINE IN THE SOUDAN.

THE TELEGRAPHIC SYSTEM OF FRENCH WEST AFRICA.

FOR many years past, public opinion in France has been alive, and very properly, to the ever increasing extension of the English submarine telegraphic system, which, at present, seems like a vast net thrown over the world.

Our own colonies, as well as those of Portugal, Germany, Holland and Spain, correspond with their respective metropolises solely through these English channels, which it would be very easy to interrupt at any moment and for any length of time.

Such enforced tutelage will bear hard upon us as long as private enterprise will not be able to obtain the confidence of the French treasury and to displace the capital still given so foolishly to foreign shadowy corporations.

A slight movement is manifesting itself in this direction. North and Central America, and even Brazil, are communicating with Brest without borrowing British cables, and the new organization will soon receive certain improvements.

A similar work is slowly elaborating on the west coast of Africa. It is certain that the day on which the cable from Saint Louis to Teneriffe is definitely acquired by France, our possessions, which extend from the White Cape to the mouth of the Niger, will have nothing to ask from the companies on the other side of the English Channel.

Without entering into considerations of political order, it is well to set forth the fact that commerce and the administration will not be slow to benefit by the new state of things through the sensible reduction of tariffs. Thus, at present, French Guinea, which was paying the West African Company 5·85 francs per word, is now sending its telegrams at 1·8 francs solely, say a diminution of 4·05 francs. The fact must not be lost sight of that this company receives, in addition, from our government, for each of the offices of Konakry, Grand Bassam, Kotonou and Libreville, an annual subsidy of 75,000 francs. Portuguese Guinea, which probably finds itself in the same situation, is thinking of asking for authority to connect her Boulam, Favim and Jeba counting houses with the telegraph line constructed last year in Casamance, a province of Senegal to the south of the Gambia.

The German and English merchants established upon the Gold Coast, at Togoland and Lagos, who are very practical people, as every one knows, will not themselves hesitate to remit their numerous dispatches to our land lines if the tariff of the submarine lines is not changed. But such fine and desirable results will be attained, and especially preserved, only at the cost of a hearty support on the part of the colonies interested.

Our readers will certainly thank us for adding a few words concerning the progressive formation of this African system, the total length of which will exceed 4,800 miles.

In the first place, and up to a recent date, the different governors who succeeded each other, both in Senegal and the Soudan, merely took into consideration the possibility of giving their administrative orders a quick transmission. In measure with the effective conquest of the country, the lines were elongated. Thus, in 1862, Faidherbe, in order to maintain Cayor, which was continually in commotion, constructed the first line between Dakar and Saint Louis, and, after this, Colonel Pinet Laprorde, along about 1868, undertook to connect with Saint Louis the military posts which were situated along the river and were too distant from headquarters.

It took ten years to force the aborigines, principally the Toucouleurs of Abdul Boubakar, our irreconcilable enemy, to allow telegraph poles to be set up around their villages.

Medina, a station founded in 1855, and which a few years afterward had to sustain a memorable siege against the bands of the prophet El Hadj Oumer, did not, in fact, communicate electrically with Saint Louis until 1885, after the laying of a cable between Barbary Point and Teneriffe.

Our expansion toward the Niger, directed by the successors of Faidherbe, the Borgnis-Desbordes, the Gallienis, and the Archinards, necessitated, as long ago as 1880, the establishment of electric conductors, which now radiate as far as to Segou and Nioro, connect with the Guinea system, and will soon join the lines of Dahomey and the Ivory Coast. This is the object that is now being pursued by Governor-General Chaudie, Colonel de Trentinian, and M. Ballot, governor of Dahomey, where the lines of the coast and those of Abomey, the immediate fruit of General Dodd's campaign, are continued to Carnotville.

Senegal, under the impulsion of its then governor, M. de Lamothe, began in 1893 the doubling of its communications with the Soudan, the correspondence of which was encumbering the sole existing line.

M. Boutrel, director of posts and telegraphs, and M. Magne, subinspector, had charge of this work, which they finished during the first month of last year.

These officials, who have just arrived in France on a sick leave, likewise, in a few months, successfully constructed a line from Konakry to Timbo and the Niger. The cost attending the execution of these vast projects is not so great as one might imagine. On the two last lines, those of Casamance-Boundou and French Guinea, the net cost per mile, inclusive of the purchase of all the exploiting material, did not exceed \$40, while at home work of the same nature costs, upon an average, over \$160.

It would take too long to enumerate the multiple causes of this great difference, but let us say in brief that it is due especially to the ease with which the supply of poles may be obtained right on the spot. Although sand prevails between Dakar and Saint Louis, and although alluviums are found in the deltas and upon the banks of the Senegal, in Saloum and Gambia, ferruginous stones form the elevations and about half the soil in the interior of Senegambia and French Guinea. The excavation of holes of from thirty inches to three feet in depth in this rock requires great effort, since the latter is so compact that it dulls the jumpers. So the wire is frequently strung upon high trees, as shown in our engraving.

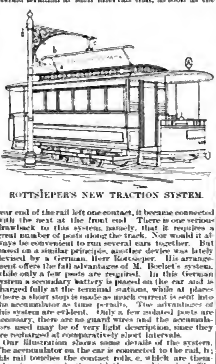
All of the operations connected with the construction of the line are performed by the natives, among whom there are sometimes some superior men, such as the old chief superintendent N'Deue N'Diaye, who, as long ago as 1862, participated in the establishment of the first line in Senegal, and was still traversing the forests of Fouta-Djallon at the head of his men last April. He is an energetic and gentle patriarch whom his men obey with veneration. Of a different character, but possessing remarkable firmness and intelligence, a second chief, Amadou Sar, has the faculty of giving endurance to the laborers, who never tire under his eyes.

Temperaments of this nature know no danger. So they did not flinch when last year the inhabitants of the fortified town of Songkounda, who had promised to arrest the work of construction, refused to give a single bottle of water to the fagged-out gangs, and made the pirogues leave the shore of the Gambia, hoping thus to prevent the crossing of the country.

The recruiting of watchmen for the ulterior maintenance of the lines is effected from among the laborers who have shown aptitude and devotion. Devotion and courage are especially indispensable to men who, often in a foreign country (Senegal alone has up to the present furnished the personnel of this category), have to keep important sections in a proper state in districts that are sometimes mountainous, as Fouta-Djallon, or arid and desert, like Boudou. Under such conditions, white men could not endure the fatigue occasioned by a continual go and come.—L'Illustration.

AN IMPROVED SYSTEM OF OVERHEAD CONNECTION FOR ELECTRIC TRACTION.

THE trolley system with overhead connection has many disadvantages, among which figures chiefly the danger to which the public is exposed in case any of the wire should break. Besides, the system necessitates the use of an unsightly net of suspending and guard wires, which do not by any means add to the appearance of the locality where the cars are run. In spite of these and other faults, the overhead system is still the most frequently used, owing to the high cost of the installation of the underground connections. Recently, however, M. Bochet has brought out an invention which, while avoiding the guard and trolley wires, yet retains all the advantages of the overhead system. He couples two or three cars together and furnishes his train with a conducting rail, which passes certain points of contact with the second terminal in such manner that a constant current is sent through the motors. This result was attained by placing posts connected to the second terminal at such intervals that, as soon as the



ROTTSIEPER'S NEW TRACTION SYSTEM.

rear end of the rail left one contact, it became connected with the next at the front end. There is one serious drawback to this system, namely, that it requires a great number of posts along the track. Nor would it always be convenient to run several cars together. But based on a similar principle, another device was lately devised by a German, Herr Rottsieper. His arrangement offers the full advantages of M. Bochet's system, while only a few posts are required. In this German system a secondary battery is placed on the car and is charged fully at the terminal stations, while at places where a short stop is made as much current is sent into the accumulator as time permits. The advantages of this system are evident. Only a few isolated posts are necessary, there are no guard wires and the accumulators used may be of very light description, since they are recharged at comparatively short intervals.

Our illustration shows some details of the system. The accumulator on the car is connected to the rail, b; this rail touches the contact rolls, c, which are themselves in communication with the second terminal. The cable carrying the current is, of course, underground. At each stop there is a post under which the car is automatically brought into the circuit. The rail, b, is hinged so that it can be flapped down into the position indicated by the dotted lines, b 1. This merely for convenience. Instead of placing the rail on the top of the car, one might also attach one to each side of the car, flapping down the one not in use.

A modification of this system has the rail on the post, instead of on the car. In cases where cars have already been run on the old system, this modification will be made use of with advantage, if the guard wires and the posts are to be discarded, for the old rods by which the current was formerly carried from wire to motor may still be used, so that one change on the car can be dispensed with.

Our engraving is from Uhland's Wochenschrift.

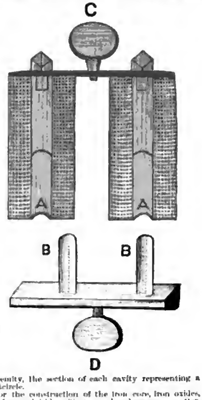
THE ORIGIN OF THE TELEPHONE.

OUR contemporary, L'Electricien, in an article under the above heading, seems to have taken it to heart that no French name has been connected with the invention of the telephone. It has, however, succeeded in satisfying itself that Charles Bourseul nearly invented it in 1854 some seven years before Reis. In an article published in L'Illustration of August 26, 1854, Bourseul raised the question of the possibility of transmitting speech by means of electric currents along a wire. The following passages, which occur in Bourseul's article, certainly show that he started work in the right direction. ". . . Imagine that one speaks near a movable plate which is so flexible that it does not lose any of the vibrations produced by the voice, and that this plate successively makes and breaks connection with a battery. You might have at a distance another plate which would make the same vibrations at the same time. It is true that the intensity of the sounds produced will be variable at the point of departure where the plate is vibrated by the voice, and constant at the point of arrival where it is vibrated by electricity, but it has been shown that this cannot alter the sounds. It is evident, at first sight, that the sounds will be reproduced at the same height in the gamut. The present state of acoustic science does not enable me to say à priori that it would be the same with syllables articulated by the human voice. . . . Any but the deaf and dumb would be able to use this means of transmission, which would require no apparatus of any sort. An electric battery, two vibrating plates, and a metallic wire would suffice. . . . Whatever happens, it is certain that, in the not very far distant future, speech will be transmitted by electricity. I have begun experiments in this direction. They are delicate, and require time and patience, but the approximations I have obtained make me anticipate a favorable result."—The Electrician.

THE SOLENOID ELECTROMAGNET.

By H. N. WARREN, Principal Liverpool Research Laboratory.

THIS powerful type of electromagnets, which, after a lengthy and exhaustive research, has just been perfected at the Research Laboratory, differs from all other magnets in the construction of the iron core; they being intended for either supporting great weights in general or the accommodation of spherical bodies, for which reception a hollow cavity is cut from each



extremity, the section of each cavity representing a semicircle.

For the construction of the iron core, iron oxides, free from sulphides, silicates, and carbonaceous matter, were selected, and reduced in an atmosphere of hydrogen, puddled through a hot blast Siemens furnace, and drawn into bars. The bars are next embedded in quicklime, brought to a full white heat, and allowed to cool in that substance. After cooling, each limb, before yoking, is drilled to within half an inch of its circumference and one quarter of its total length (if the bar be less than half an inch from starting, a corresponding allowance has naturally to be made).

The diagram above illustrates the section of a magnet with its accompanying keeper, the separate parts being further described in the specified table. The magnet was constructed to suspend a weight of ten tons, and required to be excited by a current obtainable from twenty-five boron carbon cells only.

From the above diagram it will be readily observed that when the keeper is applied with its two iron projections, B B, which are constructed of such dimensions as to exactly coincide with the openings, A A, not only is the magnetic power fully utilized, but any side slipping of the keeper is absolutely impossible. All the magnets thus described were wound with No. 14 double cotton covered wire, the winding afterward being covered with paraffined insulation, wound with thread, and varnished with best electro shellac varnish. They are at present doing excellent service in researches on diamagnetism and polarization of light.

The subjoined table will better explain a few of the more important magnets thus constructed, and giving approximate quantities of their component parts:

Length and Diameter of Core.	Weight of Primary.	Voltage Required.	Weight Supported.
2 inches × ¼	4 oz.	6	8 lb.
6 " × ½	1 lb.	10	20 "
28 " × 2	11 "	20	5 cwts.
28 " × 4	100 "	30	2 tons.
28 " × 4½	112 "	30	10 "

—The Chemical News.

NEW DRY DOCK AT HAMBURG.*

The shipbuilding yard and machine shops of Messrs. Blohm & Voss, at Hamburg, which for years have had in operation a large floating dock, known as the "Elb-dock," have just completed a new dry dock, which is the largest of its kind in existence.

This new floating dock has a carrying capacity of 17,500 tons. Its length, with the pontoons, is 624 feet 4 inches and its width 118 feet 1 inch. It is able to raise the largest merchant vessels that have thus far been built, and even the heaviest men-of-war, and consists of seven separate pontoons with high and strong sidepieces. These seven pontoons can be joined together, so as to form one concerted system. Each sidepiece contains an engine and boiler room for the pumps and electric and hydraulic machines. These two machines have condensers and 700 indicated horse power each. They drive fourteen pumps, which are capable of pumping out the dock in forty-five minutes, and thus of raising the largest vessel in this short space of time. In order to regulate the raising and the lowering of the dock, it was necessary to divide each pontoon into several watertight compartments, which are closed by means of stop valves. All these stop valves can be moved from one point by means of hydraulic power, and the depth of water in all compartments is indicated by special apparatus. By this arrangement, it is possible for one person to manage all the stop valves and to direct the pumping.

The blocks upon which the vessel rests are easily movable by machinery from the sidepieces. Altogether, this new dock is supplied with the most modern improvements, some of which were specially constructed. The dock harbor behind the shipyard has a depth of 26 feet 2 inches below 0, so that, at ordinary high tide, vessels drawing as much as 26 feet can be docked. A bridge 118 feet long connects the dock pontoon with the shore, from which the dock is therefore quite accessible. Next to the pontoon and on the quay of the shipyard there is a huge crane, which, when projected 85 feet, can raise 150 tons, and 45 tons when projected 100 feet. By means of this crane, heavy loads can be transferred directly from the shore into the dock across the largest vessels.

Owing to its peculiar construction, this great dock can, in cases of emergency or in time of war, be transferred to Brunsbüttel, at the opening of the Kaiser Wilhelm Canal, to dock vessels which have sustained heavy damages or whose draught is great. As a matter of fact, it is capable of docking vessels with a draught of 29 feet 6½ inches. No vessel with a greater draught than 27½ feet has thus far succeeded in coming up to the port of Hamburg.

Upon applying to the owners of the dock, I was informed that no fixed schedule of charges for the use of the same had been or would likely be determined. It was believed to be more profitable to make special arrangements in each case. I was given to understand that not even the German government had been furnished with any tariff of docking charges, and that for the docking of foreign vessels of war it was probable that there would be charged about $975 for the first day and $250 to $500 for each following day. Messrs. Blohm & Voss desire it to be expressly understood, however, that they do not bind themselves to these figures.

There is little doubt that this capable and energetic firm, by the construction of the new dock, have met a long-felt want in Hamburg, whose docking facilities have of late years by no means kept pace with its shipbuilding. The Hamburg American line especially will have reason to look with favor upon the new enterprise, as it will enable them to dock their express steamers and large freight boats in their home port, instead of having to send them to English or American docks.

The North German Lloyd, of Bremen, which also has some very large boats and is building more, will (as well as the German imperial navy) doubtless be glad to avail itself of these excellent facilities.

Although it is easy for persons connected with shipping to look them up in Lloyd's Register, I deem it not uninteresting to give, by way of comparison, the lengths of the largest graving docks in the world:

Docks.	Length. Feet.
Belfast	825
Birkenhead:	
No. 1	750
No. 2	930
Cardiff	600
Liverpool	768
London (Tilbury)	875
Newcastle (Wallsend)	520
Southampton	750
Antwerp	420
Cherbourg	508
Havre	535
Marseilles	503
Genoa	720
Baltimore (Simpson's)	504
Brooklyn:	
Erie No. 1	630
Erie No. 2	510
Newport News:	
At top	600
At bottom	500
Norfolk, Va	500

It will be noticed that a large proportion of these graving docks are longer than Messrs. Blohm & Voss' new floating dock, which latter, however, far exceeds the dimensions of other floating docks in existence, the length of which is seldom more than 300 to 400 feet. It seems the builders desired a dock which could be transported to almost any part of the river below this port and also one which they considered superior to any graving dock for the safe handling of large and long vessels. W. Henry Robertson, Consul.

Hamburg, April 20, 1897.

Artificial Cider.—The following is a typical formula: 25 gallons (soft) water, 3 lb. tartaric acid, 25 lb. brown sugar, and about 2 pints yeast, are put in a clean cask, and after 24 hours well roused up. Then 3 gallons of spirit are added, the cask bunged, and left for two days. This formula is variously modified, according to taste, by the use of honey, cloves, whisky, etc.

* United States Consular Report.

ARMOR PLATE PRESS.

We illustrate a double hydraulic press, constructed by Messrs. Hayward Tyler & Company, of 90 and 92 Whitecross Street, London, E. C., for bending armor plates. It is designed to work with a pressure of 2,900 lb. per square inch, acting in two inverted cylinders, each of which is provided with a return cylinder for lifting the ram when the pressure is off it. These latter cylinders are provided with screws and handwheels for regulating the height of the lift. The main cylinders have rams of 7¼ in. diameter and 25½ in. stroke, and are 3 ft. 7 in. apart, center to center. The size of the bed plate is 9 ft. 10 in. by 6 ft. 10 in. between the steel tension bars.

The head, bed, caps for the tension bars, main cylinders, and rams, with the return cylinders, are of cast iron. The return rams are mild steel. The rams are packed with U-leathers, and each is fitted with a square iron platen, secured by set screws. There are three hydraulic stop and relief valves, mounted on standards with copper pipes and bends, enabling the cylinders to be worked together or separately.—Engineering.

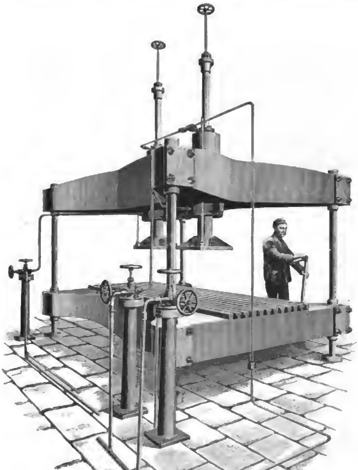
WIND AS AN AID TO FLIGHT.

By F. W. Headley, M.A.

Birds understand wind and all its vagaries, and they turn them all to account. Many problems which men of science are compelled to class among those which they hope to solve some day, or, perhaps, despair of solving, a young bird begins to work out directly he is fledged. I will take some typical cases in which a bird derives help from the wind. It will be found that the wind, if it is to lift a bird, supplementing the work of his wings, or even doing all the lifting, must either move in an upward direction or, if it does not deviate from the horizontal, it must be of unequal velocity. A wind that is unequal, or not uniform, may either be made up of currents moving at unequal rates, or it may blow now gently, now strongly. A uniform horizontal breeze cannot lift or maintain a heavy body in the air unless that body has momentum of its own. It is no better than still air, since the bird—we must try to put ourselves in his position—becomes part of the moving current. The momentum required he derives either from his own wing beats or from the inequalities of the wind. When a bird rises with wings outspread and motionless, there must be inequality, supposing that the wind is horizontal.

A lark, when he is flying upward—always singing in spite of the steepness of the incline, as if to show how easy it is—invariably faces the wind. When he turns away from it he ceases to rise and generally loses elevation. When he wishes again to rise, he turns his head toward the wind. To take another instance: a cormorant, sated at last, wishes to join his comrades who are drying their wings on a rock not far off. The wind is blowing toward the rock in question; accordingly he begins by flying in the opposite direction, so that the wind may assist him as he struggles to rise from the water. This feat accomplished, he turns round and makes all sail for his destination. The lark and the cormorant are quite right in thinking that the wind will help to lift them, but it does so only because it increases in velocity as they rise. Near the surface of the land or the sea it is retarded by friction. An anemometer reveals a very marked increase in velocity at successive elevations not far from the ground.

By means of kites experiments have been made up to a height of a thousand feet, and even there the increase continues, though it is much more gradual. Were it not for this increase of velocity with altitude, the lark, after his first jump from the ground, would, but for his own efforts, move backward with the wind. It would not lift him any more than it will lift a balloon from which the gas has escaped. But perpetually passing from a slower to a more rapid current (in theory it is convenient to divide the air into definite strata), he has always an inertia which enables the wind to lift him. He is still, so to speak, part of the slowly moving stratum below when he emerges into the rapidly moving stratum above. In fact, he illustrates the principle of the kite—inertia, which is equivalent to momentum, taking the place of the string. As long as the kite is held by the string, it will rise; cut the string, and the wind will at once resign it to the mercies of gravitation.



DOUBLE HYDRAULIC PRESS FOR BENDING ARMOR PLATES.

We see then, that if a lark wishes the wind to help him to rise, he must face it—incline his body forward, as a kite is inclined; and, further, that the inequality of the wind must give him inertia or momentum, or else his wings will have to raise him without assistance. When gulls advance at right angles to the wind without any beating of their wings, the principle applied is the same. From some slight elevation they glide downward till they are near the ground or the surface of the sea, then (possibly by a twist at the waist) they turn suddenly and face the wind, which lifts them to their former elevation; after which the process begins again.

It may be that when birds soar, i. e., rise in spirals without moving their wings, they are availing themselves at each upward step of the increasing velocity of the wind. But they sometimes attain an elevation of a mile or more, and there the increase must be a negligible quantity, if it has not at length reached the vanishing point; and, therefore, we have to look elsewhere for an explanation of soaring.

This brings us to the subject of up currents, obviously much to be desired if wing labor is to be saved; and birds, whenever such assistance is to be had, are always ready to profit by it. When the wind blows against a cliff, it is, of course, deflected upward, and gulls may sometimes be seen enjoying the fun of being lifted like a foam bubble by the up current, then descending to

be lifted again. Oftener they may be seen soaring over cliffs or hills near the shore, ascending in noble spirals without a motion of their wings. The secret lies in the upward slant of the wind. But soaring may be seen under quite different circumstances. The adjutant bird, one of the noblest of soarers, rises till he looks a mere speck or vanishes altogether, over the plains of Burma. Can there be up currents there? It is possible that, owing to the ground being unequally heated by the sun, there may be such currents here and there. But in Egypt I have seen kites soaring over fields where the young corn was growing thick and green, and where, consequently, the earth's surface was not much heated. Probably the adjutant depends on the irregularity of the wind. Even what we call a steady wind, we know by Prof. Langley's experiments, is very unsteady, and varies enormously in velocity from one moment to another. This fact the adjutant may make use of, deriving from it the indispensable inertia or momentum. As long as he can offer resistance to the breeze, not being carried by it like a balloon, but feeling it blowing in his face, so long the breeze will continue to lift him. Whenever the wind freshens he will turn and face it, and will rise like a kite. When it slackens he will sail with it, descending slightly. Obviously there will be a good deal of leeway, a phenomenon vouched for by good observers; but there will be a gain in altitude. And thus the grand bird, making even the wind, that "chartered libertine," his slave, rises higher and higher—often, no doubt, watching as he soars for carrion on the earth below, but often, probably, delighting only in the cool upper air, and in the exercise of his own skill.

To descend now to a humbler but very wonderful performance. Gulls may often be seen following in the wake of a steamer without a motion of their wings, though the wind is blowing strong in their faces. They are taking advantage of an up current. As the steamer advances, the air at the stern rushes down to prevent a vacuum being left, and this down draught rebounds off the surface of the sea and a strong up draught is formed. The gull puts himself in this up draught, which lifts him like a feather weight, then he glides downward and onward at a great pace. Meanwhile the point at which the up draught is formed advances. He soon finds himself in it again, is raised to his former elevation, and the process is repeated.

But often a gull will hover over the stern, apparently almost motionless, in reality steadily advancing with the steamer. Here, too, there must be an up current, the wind blowing at a slight angle to the steamer being deflected upward when it strikes her side. This buoys the gull up. In rising he loses way; when he advances, he descends. But he does not descend or rise rapidly, as in the case last described. Like a consummate artist, the gull conceals the art which he employs.

For the solution of this and other flight problems more observations are needed. The interest of the subject will amply repay anyone who will devote time and energy to the study of it.—Knowledge.

[Continued from SUPPLEMENT, No. 1131, page 18078.]

PERPETUAL MOTION.—III.*

THE force of gravity applied directly to the dropping arms of wheels, or to balls which roll out in troughs, fails to make such machines operate as self-movers.

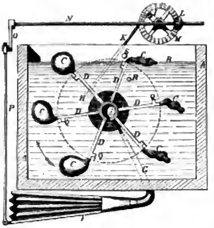


FIG. 11.

Inventors have sought often to utilize the buoyancy of floats in a similar way. The accompanying diagram illustrates this principle.

A is a cistern of water, filled as high as line B; C are six bladders, communicating by the tubes, D, with the hollow axle, E, which axle is connected with the bellows, F, by the pipe, G. H is a crank, connected with the crank, I, by the rod, K. L is a bevel wheel, M a pinion, N its shaft. O is a crank, attached to the bellows, F, by the rod, P. Q are valves with projecting levers. R and S are two projecting knobs. T is a hole in the axle, E, forming a communication with it and the lowermost bladder. The axle, E, being put in motion, is expected to carry round the bladders and tubes, and by the cranks, H and I, and the connecting rod, K, cause the wheel, L, to revolve, which, communicating a similar but accelerated motion to the pinion, M, shaft, N, and crank, O, works or blows the bellows, F, by the rod, P, from which the air enters the axle, E, by the tube, G, and passing through the hole in it at T, enters the lower bladder, C, by the tube, D; this bladder being thus rendered lighter than the space it occupies, ascends, bringing the bladder behind it over the hole in the axle, T, in like manner, and which is thereby expected to gain an ascending power, producing a similar effect on the one behind it. When one of the bladders arrives at the knob, S, the lever of the valve, Q, strikes against it, and opens the valve; when the bladder arrives at U and begins to descend, its pressure on the water drives out the air, and gives it a descending power; the knob, R, then closes the valve, Q, and prevents the entrance of any water into the bladder; by this contrivance, three of the bladders were expected to be alternately full and empty, according as they passed over the hole, T, or the knob, S.

The reason assigned for the failure of this machine was the friction, the old invincible enemy of perpetual motion seekers.

Amid all the fruitless attempts which have appeared,

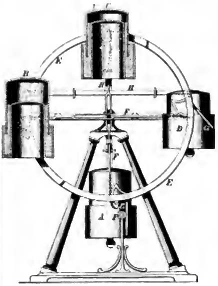

FIG. 12.

there was still one avenue to the object of pursuit, to which the common and well-known principles of hydrostatics seemed to direct the way; this was the principle that any body specifically, or bulk for bulk, lighter than common air, will rise and swim in it. Consequently, if a certain quantity of vessels are attached at equal distances, round the circumference or rim of a wheel, so contrived as that one-half of the vessels shall be exhausted on one side of the wheel, and the other half filled with air on the opposite side, in this case the exhausted vessels will attain the highest part of the wheel and the full ones the lowest. But to render the matter more explicit, we must refer to the annexed engraving, Fig. 12.

A B C D are four vessels connected to the wheels, E, by round pins which project from the vessels on each side, and enter into corresponding holes in the wheels, E. The wheels, E, are intended to revolve by the space under the vessel, B, being a vacuum, and therefore lighter than the same portion of air; a little before the vessel, B, reaches the highest point of the wheels, it begins to close, and opens the opposite vessel, D, in the same manner as the vessel, C, opens A, because the pressure of the atmosphere on the vessel, C, is equal to the pressure on A. Instead of common packing to make the vessels airtight, mercury is substituted, which has less friction, and is never out of order. The particles of mercury not being entirely free from friction, a little power is requisite to open and shut the vessels; this is expected to be effected by the rods, F, connected to the lever, G, by chains. The rods, F, give motion to other rods, H, by the rollers acting against collars on the rods, H, not shown.

The levers, G, are successively worked by sliding over the roller, P. The connecting rods, H, are so adjusted as not to draw the vessels out of their upright position, which would let the mercury escape; also, the lower vessels, A and D, are made rather larger in diameter than B C, so that the pressure of the atmosphere may counterpoise the weight of the vessels, A C and B D, with their connecting rods.

The inventor of this contrivance says:

"I doubt not in the least, that if a pneumatic machine like this were accurately executed, it would continue in perpetual motion; yet I still think the power might be greatly increased by placing the whole engine under a receiver of condensed air, say from ten to twelve atmospheres, which would weigh, if it were ten atmospheres, about twelve ounces per cubic foot."

In 1865, Herman Leonhardt, of St. Gall, Switzerland, invented a new motive power engine, which he thus describes:

"I avail myself of the property of bodies or objects of a certain specific gravity, when immersed in a fluid of a greater specific gravity, to rise or ascend to the surface of such fluid. This buoyancy represents a greater or lesser force or power, according to the greater or lesser difference between the specific gravity of the object and that of the fluid, and the size of or the displacement caused in the fluid by such object. In order to make the said objects, which I will call floats (see Fig. 13), as light as possible, and yet strong enough to resist the pressure of the water, I construct them of thin sheet metal, and in preference, in the form of tubes or hollow cylinders with flat ends. A number or series of these cylinders placed horizontally parallel to each other are hinged or linked together in a similar manner as the buckets of a chain pump; this chain of floats is passed over two sets of pulleys or disks fixed to two horizontal shafts, the one placed vertically above the other, the said pulleys being formed to suit the diameter of the floats. One-half of this chain of floats passes through the center of the tank holding the water or other fluid, and the other half passes outside the tank through the air. The floats, when in motion, enter through the bottom of the tank, in the manner hereafter described, and rise up by their buoyancy through the water; they then pass round the top pulley, descend outside the tank, and passing over the bottom pulley, again enter the tank, and so on. If cylindrical floats are used, as described, they are fixed on the connecting links half a diameter or more apart from each other; therefore, supposing the floats to be fifty centimeters in diameter, they would be placed twenty-five centimeters apart.

"Now the principal part of my invention consists in relieving the floats, when entering through the bottom of the tank, of the pressure of the water column, which pressure, if not removed or neutralized, would render the rising of the floats in the water impossible, and prevent the machine from acting. The manner in which the floats are relieved from the pressure of the water column when entering the tank is as follows: On the bottom of the tank I form an entrance chamber for the said floats of a depth equal to the diameter of a float; the bottom of the chamber and its top are each provided with double slides which open and close as the floats enter and leave the chamber. Supposing the floats to be in motion, and one of them to have arrived in the center of the chamber, a lever actuated by the moving floats or by the revolving float pulley or disk will cause the top or egress slides of the chamber to open in the same measure as the float rises; this slide, acting through another lever, will, at the same time, open a slide or valve in the side of the chamber and admit water into it, thereby bringing the water in the tank and in the chamber into equilibrium. When one-half of the float has passed through the top or egress slide, the next float will have arrived at the bottom or ingress slide, which latter will now open in proportion to the rise of the float. The egress slide will close in the same measure and at the same time shut off the communication between the tank and the chamber, which was necessary for establishing the equilibrium. At this juncture other valves connecting the chamber with pipes leading to the top of the tank are opened, and the water in the chamber, which would be detrimental to the further rise of the entering float, is withdrawn through these pipes, which I will call return pipes, by suction, and allowed to flow back into the tank above the water level; this suction is effected through the following arrangement: That portion of the top of the tank where the floats leave the water is open, but the other portion of it is covered, and a partition dividing it from the open portion is made to dip into the water to some depth, thereby rendering it a hermetically closed chamber, and the above mentioned return pipes open at a certain height above the water line into it. This chamber I call the vacuum chamber, because previous to starting the machine a vacuum or a partial vacuum must be formed in it, and afterward maintained as long as the machine is to continue in operation. The air is exhausted from the chamber by

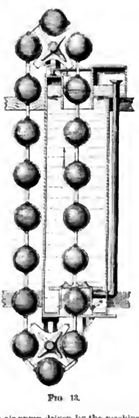

FIG. 13.

means of an air pump driven by the machine, but arranged for driving by hand for the purpose of starting the machine. By forming this vacuum the original water level in the tank will be disturbed, the water level being raised in the vacuum chamber and lowered to a corresponding extent in the open part of the tank. Supposing the tank to be of a height to hold six floats, 1, 2, 3, 4, 5 and 6, 1 being the one above described, as entering the admission chamber, it is clear that as 6 leaves the water, the water level in the open part of the tank will be lowered in proportion to the displacement previously caused by 6, and the water level in the vacuum chamber being thereby likewise lowered, it will cause a suction or drawing up of water in the return pipes, equal in quantity to the amount of water displaced in the entrance chamber by the entering float, 1. The water sucked up through the re-

* Reprinted from the SCIENTIFIC AMERICAN, 1870-71.

turn pipes will flow over into the vacuum chamber and distribute itself in the water of the tank. The ingress and egress slides of the entrance chamber are furnished with linings or packing of felt previously boiled in oil for insuring a watertight fit against the floats without much friction, and the flat ends of the floats likewise pass between sheets of felt previously boiled in oil and pressed against the flat ends by fluted rollers. The air pump is maintained in operation in order to remove the trifling quantity of atmospheric air adhering to and introduced into the tank by the entering floats. The motion communicated by the rising floats to the float pulleys or disks and shafts is further transmitted by means of belts or other gearing, in the manner usual with other motive power engines.

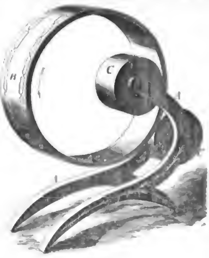

FIG. 14.

"The details of arrangement and construction of my new motive power engine may be altered or varied, but the main features of my invention consist in relieving the floats when entering the tank of the pressure of the water column by means of a vacuum chamber and parts connected therewith, as described, or their equivalents."

Only about a year since [1870] the London Mining Journal described a machine, patented in England, the essential features of which did not differ from those of Leonhardt; and what is more, expressed a favorable opinion of it.

We have received several letters with diagrams of "perpetual motion machines" from correspondents, one of which we will herewith present and defer others for future articles.

Fig. 14 is a diagram sent us by F. G. Woodward, whose address was not given in his letter.

The writer says: "It consists of a stand, A, two idler pulleys, C, between which a hollow cylindrical ring, suspended in the manner shown, is expected to revolve in the direction indicated by the arrows." The only difficulty about it is that it will not work, though it looks plausible enough.

Fig. 15 illustrates a piece of folly which, we are sorry to say, has been repeated in one form and another so

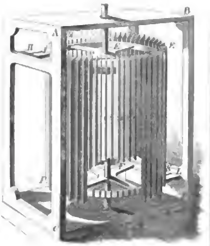

FIG. 15.

many times that it ought to be considered a standing joke, but which is nevertheless constantly turning up as a serious proposal among a class of inventors who know little or nothing of electricity and magnetism. It is the device of a Dutch inventor, Hero Hicken by name.

A B C D represents a frame of brass or wood for the machine. E F, to run in.

E and F are two brass wheels, similar and equal, fixed upon a movable axis, G.

1, 2, 3, etc., are a number of artificial magnets, placed within the teeth of the wheel all round, and as near each other as is possible, provided they do not touch; their north poles at E and their south poles at F.

H and I a. two similar and equal magnets fixed in the brass plate, A C, very near each other, but not touching.

K and L, two more fixed in the brass plate, B D.

Now, as the north pole of one magnet repels the north pole of another magnet, and attracts the south; and inversely the south pole of one magnet repels the south pole of another, and attracts the north; so the south pole, I, attracts all the north ones at E; and the north pole, H, repels all the north ones at M. In like manner, K attracts at N, and L repels at O, and by this means the whole machine, E F, is expected to move perpetually round.

Now this would be all lovely if magnets did not attract in more than one direction. Many American inventors have tried the same principle over and over, only to find their wheel standing still, and have then sighed for some septum which, interposed between a magnet and its armature, would prevent attraction while thus interposed. The editorial sanctum of the SCIENTIFIC AMERICAN has often been compelled, in answer to correspondence, to confess its ignorance of any substance of which such a septum could be constructed. Humiliating as is the confession, we never have heard of this long sought for desideratum, and what is more, we expect to leave this sublunary sphere before its discovery. But we do expect, judging from past experience, that about once a month some sanguine inventor, who thinks he has discovered the perpetual motion, "all but that one single thing," will expect us to point him the way to success by supplying to him (privately, of course) the knowledge of the septum sought.

This idea of a magnetic perpetual motion is just now the most prevalent one of all, and if what we have said shall serve to open the eyes of the many who are eagerly following what must prove to be only a delusion and a snare, our purpose will be accomplished.

Fig. 16 is an engraving of a supposed self-moving machine sent us by S. B. Davis & Company, of Detroit, Mich. They state that it is the invention of the late William Davis, of that city, who spent a great portion of his time in the attempt to make a self-moving machine.

A, in the engraving, is a tank containing water, as shown. The hollow arms, B, communicate with a hollow shaft, C, and the bellows, E; screw valves, D, being employed to increase or diminish the area of the passages in the hollow arms, B. Each of the bellows, E, carries a weight, which, during a portion of the revolution, compresses the bellows and forces the air out of

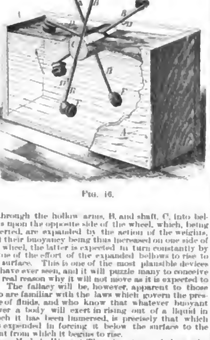

FIG. 16.

it through the hollow arms, B, and shaft, C, into bellows upon the opposite side of the wheel, which, being inverted, are expanded by the action of the weights, and their buoyancy being thus increased on one side of the wheel, the latter is expected to turn constantly by virtue of the effort of the expanded bellows to rise to the surface. This is one of the most plausible devices we have ever seen, and it will puzzle many to conceive the real reason why it will not move as it is expected to do. The fallacy will be, however, apparent to those who are familiar with the laws which govern the pressure of fluids, and who know that whatever buoyant power a body will exert in rising out of a liquid in which it has been immersed, is precisely that which was expended in forcing it below the surface to the point from which it begins to rise.

Says M. de la Hire: "There is not any of those who pretend to have found out perpetual motion, who do not agree that two weights placed in a position to move, following their natural direction in equal time, or in any way reciprocal to their weight, remain in equilibrium. Yet there is no perpetual motion scheme where one cannot draw a conclusion quite opposed to this principle; for, whatever may be pretended, perpetual motion is nothing more or less than the elevation of one weight to a certain height by the descent of another weight at the same time; and reciprocally the restitution of the first to the place where it was before its movement, by the descent of the one that had been raised, and so on ad infinitum; sometimes by means of weights, which, being raised, in their fall agitate other weights; sometimes, by means of liquid bodies, which, being raised, can run and move other parts far separated from the center of motion; from which no advantage can be derived and which is entirely contrary to the preceding principle.

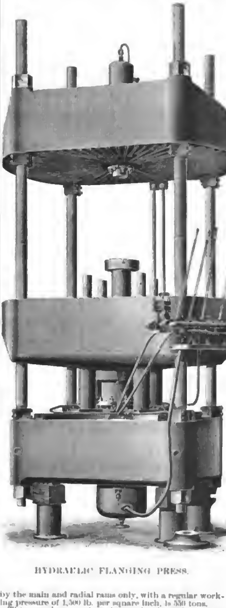
"Those who occupy themselves with this chimera find nothing but embarrassment, for generally their machines have so many weights, etc., to move them that their inventors forget always to be on their guard against the many hindrances that arise—the height, etc., of the powers employed, their natural direction, etc.—all these are sometimes so strangely jumbled together that it requires very hard work to be able rightly to distinguish them. This is one great reason that leads such persons to a false demonstration of perpetual motion; and when they propose their beautiful inventions to those who are versed in science and who cannot immediately make them see or understand in what way their reasoning is false, they then publish to the world that the very cleverest men have been convinced of the truth of their perpetual motion."

HYDRAULIC FLANGING PRESS.

HYDRAULIC flanging on locomotive boiler work, although in use for some years in this country by private railroad companies, has until recently been employed only to a limited extent in the United States. The Schenectady Locomotive Works, upon investigation of the matter about two years since, contracted for a hydraulic flanging plant with the Morgan Engineering Company, of Alliance, Ohio. The design of the press, which is illustrated herewith, was worked up very carefully with a view of adapting it to all classes of locomotive boilers in use in the United States.

The main table is 10 ft. 3 in. wide by 14 ft. long, the maximum width between the upper and lower tables being 11 ft. The minimum height between the upper and lower tables is 4 ft. and the sizes of the rams are as follows:

One main ram, 28 in. in diameter; one internal clamping ram, 14 in. in diameter; four radial clamping rams, 6 in. in diameter; one inverted top ram, 10 in. in diameter. The main columns are of steel, 7¼ in. in diameter by 27 ft. long. The total pressure exerted



HYDRAULIC FLANGING PRESS.

by the main and radial rams only, with a regular working pressure of 1,500 lb. per square inch, is 550 tons.

This press has now been in use by the Schenectady Locomotive Works for the past year and a half. The press produces, of course, work of exact uniformity, similar parts made from dies being exact duplicates in size and form, while the effect upon the steel in flanging is very much less severe than that produced by handwork with alternations of heating and flanging. It is also found that the flanges turned by the press are softer than those turned by the ordinary method of heating and flanging by hand.

The various forms of plates are heated in a large furnace, the fuel for which is oil, and after the flanging is performed the plates are still at a red-hot heat, so that the work is practically free from strains when completed.

Flanging dies have been made for their standard design of locomotives by the Schenectady Works, and the works find that quite a number of railroad companies are calling for hydraulic flanged boiler plates in their specifications—a practice which cannot be too highly recommended. The Schenectady Works are also using, as a standard practice, the pressed steel boiler

front and door, pressed steel cylinder head covers and steam chest casing covers.—Engineering.

IMPROVIDENT CIVILIZATION.*

A PLEA FOR THE APPLICATION OF SCIENTIFIC METHODS TO THE AMELIORATION OF SOCIO-ECONOMIC DEFECTS AND DISORDERS.

By RICHARD T. COLBURN.

THE responsibility you have seen fit to place upon me I will now ask you to share with me.

The controversy in respect to a bimetallic money standard, and the other as to the limits of safety for representative or currency money, are certain to be fully worked over, by the powerful vested interests concerned, in reports of commissions and printed volumes. I devote a minute or two to explaining that they are but parts of a far greater question of metrology, one also requiring for its elucidation a more exact knowledge of the laws of thought than we at present command.

The traditions of a people mould its opinions, and they change but slowly. The advance of knowledge has to overcome this inertia. Our present civilization, all types of it, are apt to be lopsided; its contour is asymmetrical; it is not abreast of the knowledge of the time, and is not yielding to mankind nearly the amount of comfort and well-being it might be made to do. To the social philosophers may be credited much of the improvement of the past hundred years. From a great number of social ills, defects and shortcomings, due chiefly to this overlapping of the childhood of the world upon its adult stages, I select a few of the more serious, which will require many centuries to correct themselves, in order to raise the inquiry among you whether it is not within the compass of human endeavor to accelerate a better state—not merely to gratify an altruistic impulse, nor yet in fulfillment of ethical ideals, but as a deliberate choice of diverging policies.

I. THE WASTE OF WARFARE AND ARMAMENT.

Ahead of its logical order, I take up the waste of war and constant preparation for war, which has haunted mankind, with few and trifling exceptions, as a malign heritage as far back as we can trace. History, whether printed in books, written on parchment, engraved on monuments, or burned in clay tablets, seems to be mainly a record of combats and glorification of warriors. Truly enough, the overrunning and subjugation of one community by another of alien looks or speech was one of the most impressive and awful calamities, surpassing in its mental impress that of earthquakes, eclipse, drought, forest or prairie fire, flood, or insect pests, because strong sinews and courage availed to give relief in one case, but not in the other. Training to arms was the ordinary occupation of life, and death by wounds, or from privations in camp, the exit, while the greatest honors were paid in primitive as in modern times to warriors.

We need not resort to any superstitious legend to account for this combative instinct; it has its analogue among the brutes which bristle up and stand on their guard at the coming of a strange figure and, in the time of scarcity, fighting for the available supply of food, shelter or females. It is even so with man; finding himself within a zone or clime-bound belt of fertility subject to periodical encroachments of the ice cap from the one direction and to the fierce suns and tropical growths on the other, hunting and fishing his principal pursuits, agriculture being nascent, there were ages when subsistence was precarious, when, along with the feræ naturæ, he was driven to the caves and trees, and had to contend for his very existence against organic and cosmic foes. The character of combatant, strengthened from generation to generation, became a first nature; he must be ever on the alert for a foe and for an occasional rival. Essentially gregarious, man could not, until very recently, associate in large numbers without engendering an artificial struggle for existence superposed on the natural.

Until the dawn of systematic agriculture, the food products of a given terrain could not keep pace with the population; not until the dawn of modern navigation was the drawing upon far distant or more fertile regions practicable; the extinction of the feeble and unskilled was therefore a foregone conclusion. Even so lately as the time of Malthus, it was held that Nature, having by her scheme of fecundity provided twenty partakers to her table spread for ten, the excess must disappear in some way by struggle or disease. It was not surprising that both philosophers and statesmen could reach the conclusion that every generation, or each quarter of a century, must have its great war in order to thin out the population to the capacity of the soil for sustaining it, or otherwise to conquer enough more territory for the purpose. The tendency of this war spirit, thus kept alive, was to diminish the population at one end of the series in order to add to it at the other. It is a late discovery that this guaranty of the sufficiency of subsistence can be more easily and effectually obtained without fighting than with it. Aside from mutual jealousy of neighbor nations, or the fear of subjugation by one or more, the policy of fighting, in order to live, can be shown to be a colossal blunder. Man need no longer exterminate his own species to escape starvation.

Had the ordeal of arms remained as it began, with a biting, scratching and wrestling, not much above the wolves, in which brute strength, sharp claws and teeth, and endurance prevailed, the perpetuation of the more warlike, and the extinction of the peaceable, must have operated to keep man closer in physique and mind to the brutes. A series of inventions of weapons, the sharpened spear, then the bow or flint tipped javelin, the arrow, the projectile, the fulminating powder, the domestication of beasts and birds—all so many triumphs of mind in the control of natural forces—enabled men to ward off the cosmic dangers and to beat back every other possible foe. Hunger and thirst and cold he had to contend with, as they had; soon he had their skins to warm him; he need not hunt his dinner before eating it; he could entrap it, and later employ the tame animals to help.

This great emotional source of wars, mutual distrust, suspicion and aggrandizement, remains with nations, as with men. When each was his own advocate, judge and executioner, the fear of combat was less than the fear of declining battle—the dread of a charge of cowardice. May we not look forward to a time when war growing out of distrust or wounded vanity shall become as obsolete among civilized people as the hunting habit, the duel, or pugilism, to which it bears a close resemblance? Perhaps, if we can demonstrate the absurdity, the folly and waste of it, we may do something to banish oppressive armaments; but the war impulse is scarcely amenable to reason, or to considerations of profit and loss; it is more vulnerable to ridicule and to the banishing of deep seated prejudices. This power of fear, rivalry and suspicion being an inherited mental trait, dating far back in man's career, nurtured by song and story, embellished by poetry and art, stimulated by a religious enthusiasm, will die slowly. Like the beliefs in fairies and witches, they are not to be uprooted by argument alone but must be outgrown.

The devolution of the fighting trait may be traced, where one would least expect to find it, among the females. Women, young and old, higher and lower, instinctively, as we say, admire physical bravery, often in preference to moral courage. The very same badges and insignia of war stir the fierce emotions more than in the males. The showy uniforms, music and bearing, the plaudits of victory, rouse them to unwonted enthusiasm. Favor is extended to the side of the conquerors, disfavor to the vanquished, as eagerly as compassion on the wounded and dead. Unconsciously it may be, women are great aids to the recruiting sergeant, and to the gladiatorial shows, pomps, pageants and circuses. The songs of all nations reflect this powerful stimulus toward battle. "J'aime que le militaire," "The bold soldier boy," is the tenor of them; and, as if to intensify and keep alive the belligerent instinct, the boy children are still given weapons as playthings. Very rare are the plaintive songs in denunciation of war. I remember one such in fashion in the first half of the century. It ran something like this:

"If I were King of France, or still better, Pope of Rome,
I'd have no fighting men abroad, no weeping maids at home,
But the world should be at peace; and if the kings must show their might,
Then should those who made the quarrels be the only ones to fight."

Traces of the same surviving habit, grown dim from disuse, are found in the fainting or swooning disposition at the sight of flowing blood. A variation of this may be found in an attack of frenzy, or fury, from the same cause. This trait is also noticeable in some animals which are excited by the red color alone. The expression "war fever" is apt; it begins in delirium and ends in lassitude and exhaustion. The persistence of the belief that "blood letting" is the natural cure for personal or social ills is a survival of the same kind. The passion for military prestige—la gloire—which so long haunted the Romans, and later the French, and is now conspicuous with their neighbors, is a fatal inheritance which lingers along with great intellectual power.

When one speaks of "firing the national heart," appeal is made to this latent instinct, and it rouses the inbred emotions in much the same way as its opposite emotion, the stampede of panic. Something of the same cruel homicidal impulse is to be seen in the old fashioned "hue and cry" against alleged infractions of decency, loyalty or sacrilege and in the craze of mobs for lynching. Strategy and artifice may avail to divert it, or lead it to harmless issues, but it cannot be extinguished at the onset by threats or any reason short of that of exhaustion by superior force. This accentuates the danger, at all times along frontier lines, of an incident of encroachment or insult which may serve as a spark to ignite combustibles. The great concern of statesmanship is to keep this latent tendency from flaming into open war. "The cancer of a long peace" no doubt reflected a state of society in which industry was dislocated, when possessions were held by the strong arm, which indeed must have been wretched to make a state of war more tolerable.

Man will fight to expel intruders upon his domain, to resist capture, to overcome sexual rivals, to protect his family and to preserve his altars and property. Modern wars spring more frequently from the latter than from all other causes combined; to be secure in the enjoyment of property, excuses and renders possible the armament of advanced nations as a reserve of police force, to maintain domestic peace and order, although the supplies are generally voted after artificial war scares. Holders of wealth are willing to be taxed to insure tranquillity at home, even at the risk of personal conscription, rather than be left at the mercy of mob violence. Such is the irony of our civilization that some of the leading nations manage to combine a treble profit by fomenting or permitting wars in which the combatants become customers for arms, ships and munitions, and also for loans of money.

An appeal to force, to establish and maintain any degree of equality or inequality of fortune, is a mistake. It puts force in the place of equity; fixes right by might; moreover, it fails of its object; armament for domestic purposes excites alarm among neighbors, who have similar pretexts, and thus the Sisyphean task is kept up. Besides, it tends to invest property holding per se with a sacredness which ought not to belong to it.

The maxim of aggressive statesmen, that "constant preparedness for war is the best security of peace," is a seductive, dangerous half truth; it is about equivalent to the old adage that every gentleman should spend an hour a day with foils and pistols to keep himself in practice against intruders, assassins or robbers. Some ultimate appeal to force, of course, there must be; but, like the enforcement of decrees of courts, it should rather be in posse than in esse.

The world presents, at the close of the century, three very instructive object lessons in the policies and prospects of three continents—Europe, Africa and America. When the first Napoleon made his menacing prophecy that "in fifty years Europe would be either all Cossack or all republican," he indicated correctly enough the two opposing forces between which it is kept in unrest and arms. He simply underestimated the time for working out. The six great powers waiting for the recovery, or expiring gasp, of their feebler neighbors, in order to obtain a share of their estates, is a sad spectacle. How many more furious struggles is history to record for the control of the Levantine shores? What a satire on civilization—not to speak of Christianity—to find the youth of Europe armed for such wanton waste! Turkey, Austria, Greece, the Balkans, Spain, Holland—is their fate to be absorption into a stronger empire? and if so, into which, and for how long? The epithet "cockpit of Europe" is one of warning to other continents.

We are permitted to identify Germany with the dominating policy of Europe because it is setting the pace, assuming the role of fencing master and armorer to sister states (and shamelessly supplies them with weapons, money and tutors to carry on the strife); and because it so successfully combines medieval feudalism, dynastic government and state church with the most advanced science and knowledge in the arts. Hence we find chancellors and reigning emperors alike claiming the usual kingly commission from Deity, the favor of the Almighty, but at the same time making open treaties with one set of powers, secret treaties with another set, and, as if in distrust of all such allies and auxiliaries, providing also the heaviest battalions and best artillery.

How unfortunate, in one sense, is the situation of the African continent in not being permitted to receive the blessings of European civilization without its attendant curses. How much better it would have been to have consolidated the whole into one, or at most two, great commonwealths with a single republican form of government, one standard of loyalty, one language, religious toleration, common jurisprudence, freedom of internal commerce, facile postal and personal intercourse, uniform measures and coinage; instead of the partition into so many reproductions of European differences of flags, creeds, politics, customs, usages, speech, each with its patch of shore front and a vast tract of hinterland to be fortified, defended and jealously watched in perpetuity. It is as if by inoculation the pest virus were poured into youthful arteries. The picturesque old cradle of Mediterranean civilization, now lying isolated from, and yet so close to, the barbaric types, deserved some nobler treatment from the enlightened powers than this selfish spoliation. The opportunity to dedicate deliberately one-quarter of the globe to peace and culture apparently has passed forever.

The dream of a peaceful consolidation of nations—a political millennium—is quite old. Fortunately there are other potent forces at work making for peace. Good will and good neighborship are also inherent emotions. Among these may be reckoned the comity of nations, perhaps also religious propaganda, foreign trade and intercommunication. The late Secretary Blaine set a notable example of the peacemaking impulse when he addressed his eloquent words to the convened representatives of American republics, counseling unification of policies, arbitration of disputes between themselves, and urging again the Fathers' doctrine of "America for Americans." This condensed motto is frequently misunderstood as implying a sort of hostile coalition against Europe calling for a hostile coalition by Europe. It is simply a forecasting desire not to be embroiled in European neighborhood disputes about boundaries, dynasties, creeds, alliances, easement rights to ports, etc., from which America can keep aloof and should be encouraged to do. That invitation, for obvious reasons, omitted the Dominion of Canada. In any future conference it is to be hoped Canadians will see their way clear to participate, in this, as in other prerogatives of self-government, as they have a joint interest in the welfare of North America politically, scientifically and economically.

That the international comity, and if you please the jubilee features, of the year may not be neglected (in which, however, science is thrust far in the background), as an American response to the very hospitable suggestion of Prof. Dicey—probably drafted before the failure of the general arbitration treaty—of a common citizenship for the people of Great Britain, her colonies and offshoots, the United States being specially included, let us say: Unworkable though it be, it is received as an expression of good-will. I venture to offer instead the counter proposition that we might have with Canada a Zollverein treaty abolishing fortifications, fleets and custom houses along the four thousand mile frontier, letting the tariff revenues be collected at the seaports. Reciprocity of language, traditions, laws, coinage, metrical systems, postage and railroad conveniences we have. By a larger interchange of merchandise and ideas, together with the freest intercourse, the benefits to be derived by both parties are so great that any sacrifice on either side would be insignificant, temporary and easily borne.

Modern warfare is becoming more and more a contest of ingenuity and material resources. Numbers or physique of combatants count for less, and even personal prowess is of less importance. Craft in strategical maneuvers remains as of old. Machines, explosives, transport, commissariat, surgical skill and adjustment of knapsack and accouterments are now paramount. Success depends also on industrial production and intellectual power. National debts, formerly supposed to be aids to peace, have become incentives to war; financiers often find a joint interest with diplomats, purveyors and soldiers, in fomenting or permitting wars to go near the point of danger for dynasties and capital. How to escape from the meshes of this combination is one of the most portentous and baffling of problems of politico-economic science. Following the analogy of guaranty and insurance corporations, it might be well for Europeans to invite proposals from the house of Rothschilds and its affiliations for a stipulated sum for which they will guaranty peace between the several members in lieu of the present onerous exactions of war loans. The financing of governments has become so large a vested industry that it demands the right to live, like some other institutions we shall have occasion to discuss, and society can neither get along comfortably with them nor extinguish them without violence. Let there be started a rumor of an invasion, blockade, or a vote for new ships and arms, by one of the number, the cabinets of Europe are in instant trepidation. The legislative assemblies at once catch the craze—up go the budgets,

* An address before the Section of Social and Economic Science of the American Association for the Advancement of Science, August, 1897. Mr. Colburn is vice-president and chairman of this section.

out go the contracts for munitions and war loans and then fluctuation in the bourses. Somebody presently discovers it was a fictitious, exaggerated alarm, and the agitation subsides, but the taxes remain just the same.

In Mulhall's recent work, "Industry and Wealth of Nations," are the figures of the national debts of Europe with an attempt to segregate that portion incurred for railroad and public works which latter are in many cases part of the military regime. The figures are impressive, but fall far short of expressing the total money cost of armament, to say nothing of the loss of public and social morale. The burden of industry is thrown upon the children and aged women, increasing the hours of labor and lowering the scale of living.

With a due sense of humiliation, we must confess that no single remedy can be found for this unhappy tangle of affairs. Parliaments, by their constitution, represent the opinions of ministerial governments, and are not themselves exempt from war fright. It is a common trick of failing ministries to strengthen their hold on power by resort to menaces and scares. The presence of one unclouded, undaunted mind at the time of panic of the multitude is a priceless desideratum; it is as cheering as the advent of a cool, competent surgeon into a room full of hysterical bystanders around a prostrate patient. Presence of mind, ridicule, satire, caricature and especially comic cartoons are more likely antidotes than argument. The disease is in good part psychic and the remedy must be of the same kind.

Again, therefore, we may say science, including its socio-economic branches, is our best hope for peace and disarmament. Among the suggestions containing more or less of promise, the following are worth mentioning:

(a) The Swedish Prof. Nobel, who accumulated an immense fortune from his nitro-glycerine inventions, has left a large fund to promote the extinction of war by making it so deadly that nations will be afraid to resort to it. Evidently when commanding generals are themselves brought within the range of unseen, and practically irresistible, dangers, they will not be so eager to seek this method of promotion. The stoutest heart quails before a stream of electricity, hot steam, asphyxiating gas or explosives rained from an air ship.

(b) Soldier and civilian are alike interested in maintaining a high standard of health and efficiency, the former having more depending on his doing so. Selected on account of his physique, the soldier should have more than the average intelligence, and if the army regulations or the instruction of the superior officers teach him how to care for himself, to moderate his passions, and endure privations, it will be a small compensation for his detachment from the industrial ranks. Sanitary and personal hygiene are of the utmost importance to the perpetuity of armies, nations and races.

(c) Continuance of the diplomatic methods, cumbrous as they are, must be assumed, although their function is becoming dimmer in the presence of telegraphs, telephones, newspapers and popular participation in national councils. Diplomacy has been at all times under suspicion of insincerity and deceit; but it has the great merit of defining in language the grievances and causes of war, which gives time for passions to cool. Armies are now massed while diplomacy is getting ready; collision comes before the causes can be stated.

(d) Courts of conciliation are an improvement in diplomacy in that they also give time for passions to subside. They do not, however, prevent armament; and armaments are ipso facto provocative of hostilities. They will still be needed as against non-arbitrating parties. The binding force of treaties, not always scrupulously observed, is being weakened by the example of conspicuous breaches. Great Britain and the United States may creditably vie with each other in setting the world an example of this mode of preventing and settling disputes.

(e) To the above, I would fain offer a further suggestion aimed at those who have the responsibility of deciding upon war or peace. The actual ruler, whether it be a parliamentary body, or a President or Chief Secretary, King or Chief Minister, Kaiser or Chancellor, Sultan or Vizier, should be required to obtain the sanction of some deliberative body, not of his own creation or selection. In addition, every such officer should be required by fundamental law to surrender his office, authority and emoluments into the hands of such an assembly, at intervals diminishing progressively with the duration of his reign; such council or parliament to be at full liberty to restore it, farther limit it, or to confer it upon a successor. Such a check upon the inebriety of power and incident flattery is needed as a safeguard against aberration of intellect or perversion of moral balance. The temptation and strain upon the faculties of one who is the fountain of honors and promotions ought not to be imposed without some such restraint. The tendency to hero worship is truly a psychological taint, pregnant with dangers enough in the populace and positively ruinous when reflected on a single mind not chosen for robustness.

In this momentous struggle of medieval types against popular forms of government in continental Europe, occupied by three millions of armed men, and seven to ten millions more subject to call, the Britons and Americans jointly owe a duty to the cause of civilization and peace, not to be swayed into the same mad folly.

(To be continued.)

A SKELETON FACTORY.*

ONE day I saw a funeral cortège leave La Roquette (the Newgate of Paris). I followed it to the cemetery of Les Champs des Navets, Ivry, and found that it was that of an Anarchist who had just paid the last penalty for his misdeeds. The rude coffin and few attendant officials reached the place of burial; the priest read the service for the dead beside the open grave, which was quickly filled in, but only the coffin was buried, for, as I afterward learned, the body was sent to the schools for dissection. It is the merciful custom in France to deliver the bodies of criminals to their relatives and friends, but when unclaimed they are sent to the dissecting pavilions for the use of medical students, after a mock funeral such as I had witnessed. Ultimately the skeletons find a place in the Anthropological Museum, where they are duly classed and labeled, so that the public, or rather the student, can study the peculiarities of criminal anatomy. Once I had obtained a clew, I quickly discovered the beginning and the end of skeletons; but the intermediate stages in which a body is stripped of flesh, muscles, nerves and tissues, and becomes transformed into a mere primal osteological structure, was still a mystery. Medical men, students, hospital officials and curators of museums were, I found, profoundly ignorant when questioned on the subject of the preparation of skeletons, but one and all unanimously repudiated the existence of a skeleton factory. It was useless to suggest that there must be a place where by some process the flesh was removed, the bones whitened and properly put together by skilled hands, as we see them in museums and studios. That this was done they admitted, with a shrug of the shoulders, but the where and the how no one would reveal.

At last, however, I found the place I wanted, and after many repulses, succeeded in getting the information required, and also in obtaining permission for an artist to make some sketches. I learned that dissection in the hospitals is not allowed. All bodies unclaimed after a certain time are sent to the dissecting pavilions of the medical schools for the use and instruction of the students, and when finished with there, they are conveyed to a place, the name and locality of which I am not at liberty to divulge. Here the head, trunk, and limbs are cleared entirely of flesh, the bones bleached and afterward treated to a course of preservatives, and finally put together by skilled anatomists. These various processes take twelve months. The factory is under government supervision. The proprietor is a rich man, the business being his sole monopoly. In addition to his place in Paris, he has two branches in London and one in New York, and a separate department for stuffing and skeletonizing animals and birds. The bodies of criminals are sent from the dissecting schools to the factory, and also many specimen bodies of different races sent home by travelers—decomposition having been first arrested by chemical preparations and injections—are received and here prepared for the anthropological museums in different parts of the world. As soon as the bodies, heads or limbs, as the case may be, reach the factory, they are placed in tanks filled with water and phenic acid, which is continually changed. They are afterward boiled in strong soda water, and again immersed in the tanks. This first stage occupies several months, and the details are far too gruesome to describe. The chemicals used in this process, and also for whitening and preserving the bones, are trade secrets.

Let us visit the stockrooms. Here are shelves full of skulls of all sizes, shapes, and races, some which, by accident, or in the interest of science, have been broken into pieces and neatly put together again with brass wires; drawers full of minute bones, and vast heaps of ribs and larger bones, mysteriously lettered and numbered. In the next room workmen are engaged in piercing the bones and preparing them for the wirers. We will pass through the laboratory and the warehouse—where we see stacks of wire of various thicknesses, springs of all kinds and sizes, stands for mounting the skeletons, and all the tools employed in putting them together—to the workrooms where the finer part of the work is done. Here the dry, fossil-like bones are united to their component parts. Some workmen are engaged in putting together hands, others feet, while several are employed in repairing skulls or fastening springs to various parts to render them movable or otherwise, according to the purpose for which they are intended and ordered. The completed limbs and skulls are then carried into an adjoining apartment, where the whole skeleton is put together, and finally mounted on a stand or attached to an iron rod, while others have a ring inserted into the skull, by which they may be suspended. From this department they are sent to the packing room and carefully boxed and dispatched to their destination, while others are placed in stock for selection by intending purchasers.

* M. Dinorben Griffith, in Pearson's Magazine.

UNITED STATES CAVIAR IN EUROPE.*

AFTER a careful investigation of the matter, based chiefly upon information received from a firm of this city which imports about 70 per cent. of the caviar entering Germany from the United States, I would express the opinion that there exists a growing and profitable market for this article in this country, as well as in other countries of Europe.

The first importation of the United States caviar into Hamburg was made twenty-nine years ago (in 1867). The shipment consisted of from 20 to 30 kegs of 135 pounds each, the price paid in America by the importers being 2 cents per pound. The caviar came from the Delaware River, from which locality comes 50 per cent. of all the United States caviar now imported here. Four thousand kegs of about 140 pounds net each might be given as the total quantity. Both lake and river caviar are brought to this country, chiefly from the Delaware River, Georgetown, D. C., Chesapeake Bay, the Fraser and Columbia rivers, the Great Lakes, and the Lake of the Woods. Lake Michigan has been entirely fished out. The supply from Lake Huron and Lake Erie has grown quite limited, while that from Lake Superior remains good. The largest quantity comes from the Lake of the Woods. Lake caviar is preferred to that from the rivers, on account of its larger roe, the latter being small and black in the river caviar.

Nearly half of the importations of United States caviar is consumed in the cheap restaurants of Berlin; three-fourths of the other half goes to Austria, and the rest to Italy and other European countries. The importations are increasing, because the article commands a better price here than in the United States and because the supplies of the Elbe and Vistula are decreasing each year. Competition with Russia is possible on account of prices and with Germany on account of the growing scarcity of the native product, as above alluded to, and the larger roe of the American caviar. Holland ships a little caviar to Germany—about 300 pounds annually; the quality, however, is poor.

* United States Consular Report.

Elbe caviar sells here for about 3 marks (72 cents) per half kilogramme (1.02 pounds); Russian sells for about 10 marks ($2.38) per half kilogramme for good medium quality, the highest grade bringing 13 to 14 marks ($3.09 to $3.33) per half kilogramme. These figures for the Russian caviar are the prices in the free harbor, that is, without duty of 75 pfennigs (17¾ cents) per half kilogramme.

Delaware caviar, I am told, cost at home, in 1893, from $25 to $28 per keg, and, in 1896, as high as $46 per keg. The prices this season are likely to equal those of last year.

Lake caviar was sold last year in the United States as high as $90 per keg of about 140 pounds net. While I cannot vouch for the statement, I have been informed by the leading firm here that the highest amount ever received in this market for lake caviar was 2⅛ marks (50⅝ cents) per half kilogramme without the duty. This price includes, however, an apparent loss in weight of 10 per cent, as the difference between American and German pounds, the freight from the lakes to Hamburg, cold storage, brokerage, commissions, etc., and 10 per cent. allowance for spoiled goods.

United States caviar is sold here by German pounds net, and, strange to remark, is salted at home with German salt, which is sent there for the purpose. It is claimed that it possesses preservative properties superior to those of American salt. Even the caviar from as far west as the Columbia River is treated with German salt.

The freight from New York to Hamburg is about 2 marks (47½ cents) per keg, or 4 marks (95 cents) if shipped in refrigerators. The high freight from the lakes to New York is an unfortunate expense to the export trade in this article. Another serious disadvantage to our product is the equal specific duty of 75 pfennigs (17¾ cents) paid by Russian and American caviar on entering Germany, which operates unfavorably, because our article is so much cheaper.

With a view to increasing the popularity of United States caviar in this and other European markets, which an effort should be made to win, it is respectfully suggested to our dealers and exporters that not less than 14 pounds of salt should be used in preserving 100 pounds of roe, to which about 2 pounds of preservative salt should be added. Under such treatment, it is confidently claimed that the caviar could not possibly spoil. The Columbia River packers who now use pine wood kegs, which are too light, should substitute those made of oak. I shall be most happy to do anything in my power to place our exporters in communication with reliable parties in this city handling United States caviar.

W. HENRY ROBERTSON, Consul.

Hamburg, February 27, 1897.

VILLAGE INDUSTRIES OF RUSSIA.

THE most noticeable feature of Russia, as distinguished from western European industry, is the more intimate connection of the former with rural economy. This means that to this day, at any rate in the majority of cases, the Russian factory hand does not abandon husbandry in his own village, but strives to maintain his connection with the land, and that trades in Russia are developed to a far greater extent in the villages than in the towns. According to a report issued from the Chancery of the Committee of Ministers, St. Petersburg, in ancient Russia the town still retained comparatively more importance for industry. In the Moscow period, however, with the strength of the power of the government, and the decline of the autonomy of the towns, trades began to be concentrated in the villages, whence craftsmen began to visit the towns only for temporary engagements on hire, or to execute the Tsar's tasks as a duty. The causes of the concentration of handicrafts in the villages were many. Town life was very feebly developed, the towns themselves differed little from villages, and in the village, husbandry alone did not always and everywhere afford a living to the peasantry, as is the case also at the present time. On the other hand, the prolonged winters, especially in central and northern Russia, left a great deal of spare time. In this village industry, or, as it is called, "koostar" industry, besides the head of the family, the other members, both men and women, take part in the work, and, not unfrequently, children of seven to ten years of age. In some trades, particularly in those of lace making and weaving, women even take the chief part. Village industries, in the course of their long history, have elaborated peculiar technical methods of their own, and a certain division of labor. Thus, for example, one part of the work is performed by children, another by adults, and a third by the aged; or in one village, one part of the article is made, in another neighboring village, another part, while in a third, the parts are put together, and in a fourth, painted. Under these conditions, koostar industry has continued to develop, notwithstanding even that the cheapness of peasant labor, and of materials, and the immense competition resulting from these causes, and the difficulty of sale, have considerably reduced the prices for these goods. There are now in all over fifty distinct kinds of village or koostar trades. Without dwelling upon their description, it will be only necessary to say that, in accordance with local conditions, the village artisans or koostars are employed above all in the manufacture of articles from wood. There are as many as 80,000 households employed in making baskets, mats, wheels, carts, buttons, spoons, and even furniture and coffins. The northern flax growing districts manufacture linen tablecloths and towels. The central districts take orders from the manufacturers for weaving the commoner cotton goods. More than 150,000 men are occupied in the preparation of leather. As many as 19,000 peasant households are employed in the manufacture of hardware. Particularly well known in the last respect are the villages of Pavlovo, Vorsma and Bezvodnoe, in the government of Nijni-Novgorod. Together with the extensive koostar districts adjoining them, these villages earn very considerable sums each year, and Pavlovo has, on account of the excellent workmanship of its cutlery, gained the name of the Russian Sheffield. If to the above mentioned industries be added the "samovar" industry in the Toola government, the painting of images on wood, lace making, and the manufacture of toys, this will complete the enumeration of the principal branches of koostar production. It is impossible to arrive at the total value of the production of such goods in Rus-

sia, from the absence of any reliable data. An equal uncertainty exists as to the exact number of persons employed in koostar industries. Some investigators fix it at 6,000,000, or four times that of the factory hands and miners. In any case, even these approximate figures are a clear indication of the importance of koostar in Russia. In some branches of industry, it stands higher, in regard to the value of the output, than that of the factories. For example, in the leather trade, the production of the manufactories is estimated at from £3,700,000 to £4,200,000, while that of the koostars reaches £5,800,000. The question as to whether koostar industry in Russia is doomed to be absorbed by manufacturing industry on a large scale is a moot one. In that country the solution of this question depends not only upon the advantages of production on a large scale over small production, in the sense of the application of improved methods, cheapening the work of machinery, etc., but also upon the need of the koostar for agricultural earnings; for so long as these earnings possess for the peasant sufficient importance for him to regard the koostar industry as a supplementary one, so long will he be in a position to reduce the price of the articles he makes almost to that of the material, and not to aspire to such a wage as would secure his independent existence. Taking, however, everything into consideration, the Russian koostar industry is stated to possess many elements for a prolonged existence and for considerable development. The most important measure for the improvement of koostar productions, and of the economic conditions of the koostars themselves, must be regarded as the extension among them of technical knowledge, of credit and of stores for the sale of koostar goods in the great towns, etc. These questions have lately been receiving the most careful attention from the government and the rural authorities (Zemstvos). There is a remarkable collection of the products of koostar industry in the St. Petersburg Agricultural Museum, and koostar exhibitions are organized in other parts of Russia.—Journal of the Society of Arts.

AN ASHANTEE KITCHEN.

THE ASHANTEES IN THE ZOOLOGICAL GARDENS AT VIENNA.

THE zoological gardens of Vienna have lately been visited by a troupe of negroes from the territory between the Gold Coast and the Ashantee country. By a stretch of the real meaning of the name, these are commonly designated Ashantee negroes.

It appears that on a former visit the negroes were so favorably impressed by Vienna and its inhabitants that they have now returned in increased numbers. They are indeed treated with such regard and sympathy that their sojourn on the banks of the Danube becomes a thoroughly enjoyable time for them. The colored men and women, and particularly the little negro children, have made themselves quite favorites with the visitors of the zoological gardens, whose number amounts to twenty or twenty-five thousand on holidays.

These Ashantees constitute a very interesting subject for study in ethnology, and all the more so because their general conduct and their performances are natural and true, free from those artifices calculated to produce sensation, which so often deteriorate similar shows.

The negroes, as we find them in Vienna, do not by any means represent the lowest and utterly uncivilized class of Africans. For centuries Portuguese, Dutchmen, English and French have traded on their shores, and have built forts and colonies. Missions, too, have been carried on, and some of the Vienna guests are Christians, and even speak a very broken English, but the mass of them have retained their primitive language and customs in their full originality. They show clearly how slow the development of culture is in those African territories.

MAN SPOOLING WOOL.

The Ashantees are accommodated in the gardens in very cleanly huts of native construction. Each hut gives shelter to one family. The whole troupe is under the rule of a chief, who is responsible for their conduct to the English consul. He carries a staff, which he has, however, no occasion to use, as his people obey him instantly on the least sign from him. He watches his people jealously for the keeping of good order and morals, and is assisted in this task by the married men and women.

Ashantee customs make married women of girls from twelve to thirteen years of age. The women, who are not, as a rule, long lived, have neither beauty nor grace. They carry their children upon their backs, in consequence of which custom they become fitted with a natural support in the form of a cushion of fat, which has been connected by analogy with the similar decorations of the burden bearer of the desert—the camel.

These negro women are very cleanly, and the picturesque folds which constitute their dress are always of absolute purity. Among the children some charming creatures are found. The little boys and girls show a remarkably gay and peaceful disposition, and behave exceedingly well in the school, which is held by a negro schoolmaster, and where they do their writing in kneeling posture. In their spare time they amuse themselves in various ways, very much like white children. Some of the men follow various occupations as artisans, and, in spite of their primitive tools, turn out very creditable products. Thus some are smiths, others weave mats and baskets, some are boat builders, and even goldsmiths. One of our illustrations shows a man spooling wool. His device for doing this work is very ingenious. In one hand he holds the spool, a rotating stick supported at one end in his hand and at the other on the ground. We see that he has even taken the trouble and had the good sense to furnish this part of the apparatus with a small fly wheel. The second part of the apparatus shows how simple things may serve for good ends. Here a bottle makes a very good bearing for the rotating reel from which the wool is wound by giving it an occasional impulse.

The women, carrying their children, are employed in the kitchen, cooking the meals on primitive fireplaces. The yam root, which forms the chief food in their native country, is supplanted during their stay in Europe by the potato, which is mashed and served in balls. The kitchens are not particularly appetizing, but one step they have already advanced, for enameled tin pots have come into use. Our illustration shows a group of women engaged in various kinds of kitchen work. We see one churning, two others peeling potatoes, while a third, smoking a pipe, and carrying a child on her back, is apparently taking a rest.

The chief attraction, however, of this negro colony is found in the original performances of the Ashantees, which include singing and dancing, a procession led by the chief, and battle scenes. In the singing and the playing of their musical instruments these negroes show an untiring zeal. Most of them belong to the musician caste, which in Africa play a similar part as the gypsies do in Hungary, except that the services of the latter are required only on joyful occasions, while the former do not by any means restrict their productions to such times. They make their music part of their religious ceremonies, and consequently resort to it on all occasions. Their dances, too, are religious rites. One of them, if once begun, must be continued till nightfall, no matter how early in the day it may have

commenced. Our illustration represents some of these blacks engaged in the performance of one of their dances, known as the handkerchief dance.

It is in the evening, when the day's work is over, that the good time for the negroes sets in. Attentions, which are not wanting by day, are now lavishly poured on them. Men and women, but particularly children, are asked to partake of the evening meal with the white visitors. It is a comic sight to find the majority of tables of the park restaurant occupied by a motley company of black and white, to see richly dressed ladies and gentlemen joking playfully with little colored children. The older children accept these attentions with simple grace, and enjoy greatly the privilege of eating with knife and fork.

This visit of the Ashantees has proved a help in need to the zoological gardens at Vienna, for affairs had taken a very bad turn, and a total breakdown was feared, while under the present circumstances a promising turn of the tide has set in, which, it is hoped, will enable the institution to live through the apparently hard times.

Our illustrations are taken from Illustrirte Zeitung.

THE HANDKERCHIEF DANCE.

THE BRITISH ASSOCIATION—ADDRESS IN GEOGRAPHY.

THE address in Section E was delivered by Dr. J. Scott Keltie, Sec. R.G.S., who, after some preliminary remarks, said: There is a prevalent belief that geographers have nothing more to learn in Europe—that that old continent has been thoroughly explored. It is true that nearly every country in Europe has been, or is being, trigonometrically surveyed. Except some parts of the Balkan Peninsula and north of Russia, the topography of the continent has been accurately mapped on scales and by methods sufficient at least for the purposes of the geographer. Yet there are districts in the Balkan Peninsula—for example, Albania—which are as vaguely known as Central Africa. But it is a delusion to think that because a country has been fully mapped the occupation of the geographer is gone. It is only when a region at large is adequately mapped that the work of geographical research begins. The student, with a satisfactory map of a definite district as his guide, will find on the spot abundant occupation in working out its geographical details, the changes which have taken place in its topography, and the bearing of its varied features upon its history, its inhabitants, its industries. This kind of work has been in progress in Germany for over ten years, under the auspices of the Central Commission for the Scientific Geography (Landeskunde) of Germany, with its seat at Stuttgart. Under the collective title of "Forschungen zur Deutschen Landes und Volkskunde," a long series of monographs by specialists has been published, dealing in minute detail with one or more aspects of a limited district. Thus we have such memoirs as "The Plain of the Upper Rhine and its Neighboring Mountains," by Dr. Richard Lepsius; "The Towns of the North German Plain in Relation to the Configuration of the Ground," by Dr. Hahn; "The Munich Basin: a Contribution to the Physical Geography of Southern Bavaria," by C. Gruber; "The Mecklenburg Ridges and their Relation to the Ice Age," by Dr. E. Geinitz; "The Influence of the Mountains on the Climate of Central Germany," by R. Assmann; "The Distribution and Origin of the Germans in Silesia," by Dr. K. Weinhold; "Mountain Structure and Surface Configuration of Saxon Switzerland," by Dr. A. Hettner; "The Erzgebirge: an Orometric-Anthropogeographical Study," by Dr. J. Burgkhardt; "The Thuringian Forest and its Surroundings," by Dr. H. Pröscholdt, and so forth. There is thus an inexhaustible field for scientific geography in its most comprehensive sense, a series of problems which may take generations to work out. In a less systematic way we have similar monographs by French geographers. One or two attempts, mainly by teachers, have been made in England to do similar work, but the impression generally produced is that the authors have not been well equipped for the task. I am glad to say that in England the Royal Geographical Society has initiated a movement for working out in a systematic fashion what one may call the regional geography of the British Islands on the basis of the one inch maps of the Ordnance Survey. It is a strange thing that the geography of the mother country has never yet been systematically worked out. Taking the sheets of the Ordnance Survey map as a basis, it is proposed that each district should be thoroughly investigated, and a complete memoir of moderate dimensions systematically compiled to accompany the sheet, in the same way that each sheet of the Geological Survey map has its printed text. It is a stupendous undertaking that would involve many years' work, and the results of which, when complete, would fill many volumes. But it is worth doing; it would furnish the material for an exact and trustworthy account of the geography of Britain on any scale, and would be invaluable to the historian, as well as to others dealing with subjects having any relation to the past and present geography of the land. The librarian of the society, Dr. H. R. Mill, has begun operations on a limited area in Sussex. When he has completed this initial memoir, it will be for the society to decide whether it can continue the enterprise or whether it will succeed in persuading the government to take the matter up. I refer to work of this kind mainly to indicate what, in my conception, are some of the problems of the future which geography has to face, even in fully surveyed countries. Even were the enterprise referred to carried out, there would be room enough for special researches in particular districts. But while there is an inexhaustible field in the future for geographical work in the direction I have indicated, there is no doubt that much still remains to be done in the way of exploring the unknown, or little known, regions of the globe. Let us briefly refer to the problems remaining to be solved in this direction. Turning to the continent of Asia, we find that immense progress has been made during the past 60 years. In the presidential address given 60 years ago, already referred to, Mr. Hamilton says of Asia: "We have only a very general knowledge of the geographical character of the Burman, Chinese and Japanese empires; the innumerable islands of the latter are still, except occasionally, inaccessible to European navigators. Geographers hardly venture on the most loose description of Tibet, Mongolia, or Chinese Tartary, Siam, and Cochin China." Since then the survey of India—one of the greatest enterprises undertaken by any state—has been completed, and is being rapidly extended over Burma. But I need not remind you in detail of the vast changes that have taken place in Asia during these years, and the immense additions that have been made to our knowledge of its geography. Exploring activity in Asia is not likely to cease, though it is not to be expected that its inhospitable center will ever be so carefully mapped as have been the mountains of Switzerland. The most important desiderata, so far as pioneer exploration in Asia is concerned, may be said to be confined to two regions.* In Southern and Central Arabia there are tracts which are entirely unexplored. It is probable that this unexplored region is in the main a sandy desert. At the same time, it is, in the south at least, fringed by a border of mountains whose slopes are capable of rich cultivation, and whose summits the late Mr. Theodore Bent found, on his last and fatal journey, to be covered with snow. In exploration, as in other directions, it is the unexpected that happens; and if any traveler cared to face the difficulties—physical, political and religious—which might be met with in Southern and Central Arabia, he might be able to tell the world a surprising story. The other region in Asia where real pioneer work still remains to be done is Tibet and the mountainous districts bordering it on the north and east. Lines of exploration have in recent years been run across Tibet by Russian explorers like Prejevalsky, by Rockhill, Prince Henry of Orleans and Bonvalot, by Bower, Littledale, Welby, and Malcolm. From the results obtained by these explorers we have formed a fair idea of this, the most extensive, the highest, and

THE MOST INHOSPITABLE PLATEAU IN THE WORLD.

A few more lines run in well selected directions would probably supply geography with nearly all she wants to learn about such a region, though more minute exploration would probably furnish interesting details as to its geological history. The region lying to the north of the Himalayan range and to the south of the parallel of Lhasa is almost a blank on the map, and there is ample room here for the enterprising pioneer. The forbidden city of Lhasa is at present the goal of several adventurers, though, as a matter of fact, we cannot have much to learn in addition to what has been revealed in the interesting narrative of the native Indian traveler, Chandra Das. The magnificent mountain region on the north and east of Tibet furnishes a splendid field for the enterprising explorer. Mrs. Bishop recently approached it from the east, through Szechuen, and her description of the romantic scenery and the interesting non-Mongolian inhabitants leaves us with a strong desire to learn more. On the southeast of Tibet is the remarkable mountainous region, consisting of a series of lofty parallel chains, through which run the upper waters of the Yangtse, the Mekong, the

* For part of what follows with reference to Asia, I am indebted to a valuable memorandum on the subject drawn by the late Mr. Ney Elias.

Salwin, and the Irawady. This last named river, recent exploration has shown, probably does not reach far into the range. But it will be seen by a glance at a map that the upper waters of the other rivers are carried far into the heart of the mountains. But these upper river courses are entirely conjectural, and have given rise to much controversy. There is plenty of work here for the explorer, though the difficulties, physical and political, are great. But besides these great unexplored regions, there are many blanks to be filled up in other parts of Asia, and regions which, though known in a general way, would well repay careful examination. There is the mountain tract between the upper Zarafshan River and the middle course of the Sarkhab tributary of the Oxus, and the country lying between that and the Oxus. There is the great Takla-Makan Desert in Chinese or Eastern Turkistan, part of which has recently been explored by Russian expeditions, and by that young and indefatigable Swedish traveler, Dr. Sven Hedin. It is now one of the most forbidding deserts to be found anywhere; but it deserves careful examination, as there are evidences of its once having been inhabited, and that at no very remote period. It is almost surrounded by the Tarim, and on its eastern edge lies Lob-nor, the remarkable changes in which have been the subject of recent investigation. As readers of Dr. Nansen's "Voyage of the Fram" will remember, the Siberian coast is most imperfectly mapped; of course, it is a difficult task, but it is one to which the Russian government ought to be equal. China has on paper the appearance of being fairly well mapped; but, as a matter of fact, our knowledge of its mountain ranges and of its great river courses is, to a large extent, extremely vague. All this awaits careful survey. In Northeastern Manchuria and in many parts of Mongolia there are still blanks to be filled up, and mountain and river systems to be surveyed. In the Malay Peninsula, and in the great array of islands in the east and southeast of Asia—Sumatra, Borneo, the Philippines—much work still remains to be done. Thus, for the coming century, there will be abundance of work for explorers in Asia. Coming to

THE MAP OF AFRICA,

we find a marvelous transformation during the last sixty years, and mainly during the last forty years, dating from Livingstone's memorable journey across the continent. Though the north of Africa was the home of one of the oldest civilizations, and though on the shores of the Mediterranean Phenicians, Carthaginians, Greeks, and Romans were at work for centuries, it has only been within the memory of many of us that the center of the continent, from the Sahara to the confines of Cape Colony, has ceased to be an unexplored blank. This blank has been filled up with bewildering rapidity. Great rivers and lakes and mountains have been laid down in their main features, and the whole continent, with a few unimportant exceptions, has been parceled out among the powers of Europe. But much still remains to be done ere we can form an adequate conception of what is in some respects the most interesting and the most intractable of the continents. Many curious problems still remain to be solved. The pioneer work of exploration has to a large extent been accomplished; lines have been run in all directions; the main features have been blocked out. But between these lines the broad meshes remain to be filled in, and to do this will require many years of careful exploration. However, there still remain one or two regions that afford scope for the adventurous pioneer.

To the south of Abyssinia and to the west and northwest of Lake Rudolf, on to the Upper Nile, is a region of considerable extent, which is still practically unknown. Again, in the Western Sahara there is an extensive area, inhabited mainly by the intractable Tuaregs, into which no one has been able to penetrate, and of which our knowledge is extremely scanty. Even in the Central Sahara there are great areas which have not been traversed, while in the Libyan Desert much remains to be done. These regions are of interest almost solely from the geographical and geological standpoints. But they deserve careful investigation, not only that we may ascertain their actual present condition, but in order, also, that we may try to discover some clews to the past history of this interesting continent. Still, it must be said that the great features of the continent have been so fully mapped during the last half century that what is required now is mainly the filling in of the details. This is a process that requires many hands and special qualifications. All over the continent there are regions which will repay special investigation.

Quite recently an English traveler, Mr. Cowper, found not far from the Tripoli coast miles of magnificent ruins, and much to correct on our maps. If only the obstructiveness of the Turkish officials could be overcome, there is a rich harvest for anyone who will go to work with patience and intelligence. Even the interior of Morocco, and especially the Atlas Mountains, are but little known. The French, both in Tunis and Algeria, are extending our knowledge southward. All the powers who have taken part in the scramble for Africa are doing much to acquire a knowledge of their territories. Germany, especially, deserves praise for the persistent zeal with which she has carried out the exploration of her immense territories in East and West Africa. The men she sends out are unusually well qualified for the work, capable not simply of making a running survey as they proceed, and taking notes on country and people, but of rendering a substantial account of the geology, the fauna, the flora, and the economic conditions. Both in the French and the British spheres good work is also being done, and the map of Africa being gradually filled up. But what we especially want now are men of the type of Dr. J. W. Gregory, whose book on the Great Rift Valley is one of the most valuable contributions to African geography ever made.

If men of this stamp would settle down in regions like that of Mount Ruwenzori, or Lake Rudolf, or the regions about Lakes Bangweolo and Tanganyika, or in the Atlas, or in many other regions that could be named, the gains to scientific geography, as well as to the economical interests of Africa, would be great. An example of work of this kind is seen in the discoveries made by a young biologist trained in geographical observation—Mr. Moore, on Lake Tanganyika. There he found a fauna which seems to afford a key to the past history of the center of the continent, a fauna which, Mr. Moore maintains, is essentially of a soft water type. Mr. Moore, I believe, is inclined to maintain that the ancient connection of this part of Africa with the ocean was not by the west, as Joseph Thomson surmised, but by the north, through the Great Rift Valley of Dr. Gregory; and he strongly advocates the careful examination of Lake Rudolf as the crucial test of his theory. It is to be hoped that he, or some one equally competent, will have an opportunity of carrying out an investigation likely to provide results of the highest importance. I have dwelt thus long on Africa, because it will really be one of the great geographical problems of the coming century. Had it been as suitable as America or Australia, we may be sure it would not have remained so long neglected and despised by the European peoples as it has done. Unfortunately for Africa, just as it has been circumnavigated, and just as Europeans were beginning to settle upon its central portion and trying to make their way into the interior, Columbus and Cabot discovered

A NEW WORLD.

Probably nothing could be more marked than the progress which America has made since its rediscovery 400 years ago, and the stagnation of Africa which has been known to Europe since long before the beginning of history. During these 400 years North America at least has been very thoroughly explored. The two great nations which divide North America between them have their government surveys, which are rapidly mapping the whole continent and investigating its geology, physical geography and its natural resources. I need hardly tell an audience like this of the admirable work done by the survey of Canada under Sir William Logan, Dr. Selwyn, and his successor, Dr. George Dawson; nor should it be forgotten that under the Lands Department much excellent topographical work has been carried out by Captain Deville and his predecessors. Still, though much has been done, much remains to be done. There are large areas which have not as yet even been roughly mapped. Within quite recent years we have had new regions opened to us by the work of Dawson and Ogilvie on the Yukon, by Dr. Bell in the region to the south of Hudson's Bay, by the brothers Tyrrell in the Barren Lands on the west of the same bay, by O'Sullivan beyond the sources of the Ottawa, and by Low in Labrador. But it is not so long since that Dr. Dawson, in reviewing what remains to be done in the Dominion in the way of even pioneer exploration, pointed out that something like a million square miles still remained to be mapped. Apart from the uninhabitable regions of the north, there are, as Dr. Dawson pointed out, considerable areas which might be turned to profitable agricultural and mining account of which we know little, such areas as those which have been recently mapped on the south of Hudson's Bay by Dr. Bell, and beyond the Ottawa by Mr. O'Sullivan. Although the eastern and western provinces have been very fully surveyed, there is a considerable area between the two lying between Lake Superior and Hudson's Bay which seems to have been so far almost untouched. A very great deal has been done for the survey of the rivers and lakes of Canada. I need hardly say that in Canada, as elsewhere in America, there is ample scope for the study of many problems in physical geography—past and present glaciation and the work of glaciers, the origin and regime of lake basins, the erosion of river beds, the oscillation of coast lines.

Happily, both in Canada and the United States, there are many men competent and eager to work out problems of this class, and in the reports of the various surveys, the transactions of American learned societies, in scientific periodicals, in separate publications, a wealth of data has already been accumulated of immense value to the geographer. Every geologist and geographer knows the important work which has been accomplished by the various surveys of the United States, as well as by the various State surveys. The United States coast survey has been at work for more than half a century, mapping not only the coast, but all the navigable rivers. The lake survey has been doing a similar service for the shores of the great lakes of North America. But it is the work of the Geological Survey which is best known to geographers—a survey which is really topographical as well as geological, and which, under such men as Hayden, King and Powell, has produced a series of magnificent maps, diagrams and memoirs, of the highest scientific value and interest. Recently this survey has been placed on a more systematic basis; so that now a scheme for the topographical survey of the whole of the territory of the United States is being carried out. Extensive areas in various parts of the States have been already surveyed on different scales. It is to be hoped that in the future, as in the past, the able men who are employed on this survey work will have opportunities of working out the physiography of particular districts, the past and present geography of which is of advancing scientific interest. Of the complete exploration and mapping of the North American continent we need have no apprehension; it is only a question of time, and it is to be hoped that neither of the governments responsible will allow political exigencies to interfere with what is really a work of national importance. It is when we come to Central and South America that we find ample room for the unofficial explorer. [I am indebted for much of the information relative to South America to a valuable memorandum by Sir Clements R. Markham and Col. G. E. Church.] In Mexico and the Central American states there are considerable areas of which we have little or only the vaguest knowledge. In South America there is really more room now for the pioneer explorer than there is in Central Africa. In recent years the Argentine Republic has shown a laudable zeal in exploring and mapping its immense territories, while a certain amount of good work has also been done by Brazil and Chile. Most of our knowledge of South America is due to the enterprise of European and North American explorers.

Along the great river courses our knowledge is fairly satisfactory, but the immense areas, often densely clad with forests, lying between the rivers are almost entirely unknown. In Patagonia, though a good deal has lately been done by the Argentine government, still, in the country between Punta Arenas and the Rio Negro, we have much to learn; while on the west coast range, with its innumerable fjordlike inlets, its islands and peninsulas, there is a fine field for the geologist and physical geographer. Indeed, throughout the whole range of the Andes systematic exploration is wanted, exploration of the character of the excellent work accomplished by Whymper in the region around Chimborazo. There is an enormous area lying to the east of the Northern Andes, and including their eastern slopes, embracing the eastern half of Ecuador and Colombia, Southern Venezuela, and much of the country lying between that and Northern Bolivia, including many of the upper tributaries of the Amazon and Orinoco, of which our knowledge is of the scantiest. Even the country lying between the Rio Negro and the Atlantic is but little known. There are other great areas, in Brazil and in the Northern Chaco, which have only been partially described, such as the region whence the streams forming the Tapajos and the Paraguay take their rise, in Mato Grosso. A survey and detailed geographical and topographical description of the whole basin of Lake Titicaca is a desideratum. In short, in South America there is a wider and richer field for exploration than in any other continent. But no mere rush through these little-known regions will suffice. The explorer must be able not only to use his sextant and his theodolite, his compass and his chronometer. Any expeditions entering these regions ought to be able to bring back satisfactory information on the geology of the country traversed, and of its fauna and flora, past and present; already the revelations which have been made of the past

GEOGRAPHY OF SOUTH AMERICA

are of the highest interest. We have remains of extinct civilizations to deal with, and although much has been done in this direction, much remains to be done; and in the extensive region already referred to, the physique, the traditions, and the customs of the natives will repay careful investigation. The southern continent of Australia is in the hands of men of the same origin as those who have developed to such a wonderful extent the resources of Canada and the United States, and therefore we look for equally satisfactory results so far as the characteristics of that continent permit. The five colonies which divide among them the three million square miles of the continent have each of them efficient government surveys, which are rapidly mapping their features and investigating their geology. But Australia has a trying economic problem to solve. In none of the colonies is the water supply quite adequate; in all are stretches of desert country of greater or less extent. The center and western half of the continent is covered by a desert more waterless and more repellent than even the Sahara; so far as our present knowledge goes, one-third of the continent is uninhabitable. This desert area has been crossed by explorers, at the expense of great sufferings, in various directions, each with the same dreary tale of almost featureless sandy desert, covered here and there with spinifex and scrub, worse than useless. There are hundreds of thousands of square miles still unknown; but there is no reason to believe that these areas possess any features that differ essentially from those which have been found along the routes that have been explored. There have been one or two well-equipped scientific expeditions in recent years that have collected valuable data with regard to the physical characteristics, the geology and biology of the continent, and it is in this direction that geography should look for the richest results in the future. There remains much to be done before we can arrive at satisfactory conclusions as to the physical history of what is, in some respects, the most remarkable land area on the globe.

Though the surface water supply is so scanty, there is reason to believe that underneath the surface there is an immense store of water. In one or two places in Australia, especially in Western Queensland, and in New South Wales, this supply has been tapped with satisfactory results; millions of gallons a day have been obtained by sinking wells. Whether irrigation can ever be introduced on an extensive scale into Australia depends upon the extent and accessibility of the underground water supply, and that is one of the geographical problems of the future in Australia. New Zealand has been fairly well surveyed, though a good deal remains to be done before its magnificent mountain and glacier system is completely known. In the great island of New Guinea both the British and the Germans are opening the interiors of their territories to our knowledge, but the western and much larger portion of the island presents a large field for any explorer who cares to venture into its interior. The marvelous success which has attended Dr. Nansen's daring adventure into the Arctic seas has revived a widespread interest in

POLAR EXPLORATION.

Nansen has almost solved the North Polar problem. That some one will reach the Pole at no distant date is certain. Nansen has shown the way, and the legitimate curiosity of humanity will not rest satisfied till the goal be reached. But Arctic exploration does not end with the attainment of the Pole. Europe has done her share on her own side of the Pole; what about the side which forms the Hinterland of North America, and specially of Canada? To the north of Europe and Asia we have the scattered groups of islands Spitzbergen, Franz Josef Land, Novaya Zemlya and the New Siberian Islands. To the north of America we have an immense archipelago, the actual extent of which is unknown.

Nansen and other Arctic authorities maintain that the next thing to be done is to complete exploration on the American side—to attempt to do for that half of the North Polar region what Nansen has done for the other half. It may be that the islands which fringe the northern shores of the New World are continued far to the north; if so, they would form convenient stages for the work of a well-equipped expedition. It may be that they do not go much farther than we find them on our maps.

Whatever be the case, it is important, in the interest of science, that this section of the Polar area be examined; that as high a latitude as possible be attained; that soundings be made to discover whether the deep ocean extends all round the Pole. It is stated that the gallant Lieut. Peary has organized a scheme of exploring this area which would take several years to accomplish. Let us hope that he will be able to carry out his scheme. Meantime, should Canada look on with indif-

ference? She has attained the standing of a great and prosperous nation. She has shown the most commendable zeal in the exploration of her own immense territory. She has her educational, scientific, and literary institutions, which will compare favorably with those of other countries; her press is of a high order, and she has made the beginnings of a literature and an art of her own. In these respects she is walking in the steps of the mother country. But has Canada not reached a stage when she is in a position to follow the maternal example still further? What has more contributed to render the name of Great Britain illustrious than those great enterprises which for centuries she has sent out from her own shores, not a few of them solely in the interests of science? Such enterprises elevate a nation and form its glory and its pride. Surely Canada has ambitions beyond mere material prosperity, and what better beginning could be made than the equipment of an expedition for the exploration of the seas that lie between her and the Pole? I venture to throw out these suggestions for the consideration of those who have at heart the honor and glory of the great Canadian Dominion. Not only has an interest in Arctic exploration been revived, but in Europe at least an even greater interest has grown up in the exploration of the region around the opposite pole of the earth, of which our knowledge is so scanty.

Since Sir James C. Ross' expedition, which was sent out in the year 1839, almost nothing has been done for Antarctic research. We have here to deal with conditions different from those which surround the North Pole. Instead of an almost landless ocean, it is believed by those who have given special attention to the subject that a continent about the size of Australia covers the South Polar region. But we do not know for certain, and surely, in the interests of our science, it is time we had a fairly adequate idea of what are the real conditions. We want to know what is the extent of that land, what are its glacial conditions, what is the character of its geology, what evidence exists as to its physical and biological conditions in past ages? We know there is one lofty active volcano; are there any others? Moreover, the science of terrestrial magnetism is seriously impeded in its progress because the data in this department from the Antarctic are so scanty. The seas around this continent require to be investigated both as to their depth, their temperature, and their life. We have here, in short, the most extensive unexplored area on the surface of the globe. For the last three or four years the Royal Geographical Society, backed by other British societies, have been attempting to move the home government to equip an adequate expedition to complete the work begun by Ross sixty years ago, and to supplement the great work of the Challenger. But though sympathy has been expressed for Antarctic exploration, and though vague promises have been given of support, the government is afraid to enter upon an enterprise which might involve the services of a few naval officers and men. We need not criticise this attitude. But the Royal Geographical Society has determined not to let the matter rest here. It is now seeking to obtain the support of public-spirited men for an Antarctic expedition under its own auspices. It is felt that Antarctic exploration is peculiarly the work of England, and that if an expedition is undertaken, it will receive substantial support from the great Australasian colonies, which have so much to gain from a knowledge of the physical condition of a region lying at their own doors, and probably having a serious influence on their climatological conditions. Here, then, is one of the greatest geographical problems of the future, the solution of which should be entered upon without further delay. It may be mentioned that a small and well-equipped Belgian expedition has already started, mainly to carry out deep sea research around

THE SOUTH POLAR AREA.

But our science has to deal not only with the lands of the globe; its sphere is the whole of the surface of the earth, and all that is thereon, so far, at least, as distribution is concerned. The department of oceanography is a comparatively new creation; indeed, it may be said to have come definitely into being with the famous voyage of the Challenger. There had been expeditions for ocean investigation before that, but on a very limited scale. It has only been through the results obtained by the Challenger, supplemented by those of expeditions that have examined more limited areas, that we have been able to obtain an approximate conception of the conditions which prevail throughout the various ocean depths—conditions of movement, of temperature, of salinity, of life. We have only a general idea of the contours of the ocean bed, and of the composition of the sediment which covers that bed. The extent of the knowledge thus acquired may be gauged from the fact that it occupies a considerable space in the fifty quarto volumes—the "Challenger Publications," which it took Dr. John Murray twenty years to bring out. But that great undertaking has only, as it were, laid down the general features of the oceanic world. There is plenty of room for further research in this direction. Our own surveying ships, which are constantly at work all over the world, do a certain amount of oceanic work, apart from mere surveying of coasts, and islands, and shoals. In 1895 one of these found in the South Pacific soundings deeper by 300 fathoms than the deepest on record, that found twenty years earlier by the Tuscarora to the northeast of Japan. The deepest of these new soundings was 5,155 fathoms. In the interests of science, as well as of cable laying, it is desirable that our surveying ships should be encouraged to carry out work of this kind more systematically than they do at present. This could surely be arranged without interfering with their regular work. We want many more observations than we now have, not only on ocean depths, but on the nature of the ocean bed, before we can have a satisfactory map of this hidden portion of the earth's surface, and form satisfactory conclusions as to the past relations of the ocean bed with what is now dry land. I believe the position maintained by geologists, that from the remote period when the great folds of the earth were formed, the present relations between the great land masses and the great oceans have been essentially the same; that there have no doubt been great changes, but that these have been within such limits as not to materially affect their relations as a whole. This is a problem which further oceanic research would go a long way to elucidate. That striking changes are going on at the present day, and have been going on within the human period, cannot be doubted. Some coast lines are rising; others are falling. Prof. John Milne, our great authority on seismology, has collected an extremely interesting series of data as to the curious changes that have taken place in the ocean bed since telegraphic cables have been laid down. The frequent breakages of cables have led to the examination of the suboceanic ground on which they have been laid, and it is found that slides and sinkings have occurred, in some cases amounting to hundreds of fathoms. These, it is important to note, are on the slopes of the continental margin, or, as it is called, the continental shelf, as, for example, off the coast of Chile. It is there, where the earth's crust is peculiarly in a state of unstable equilibrium, that we might expect to find such movements; and, therefore, soundings along the continental margins, at intervals of, say, five years, might furnish science with data that might be turned to good account. Another important problem to attack, and that in the near future, is that of oceanic islands. I say in the near future, because it is to be feared that very few islands now remain unmodified by contact with Europeans. Not only have the natives been affected, both in physique and in customs, but the introduction of European plants and animals has to a greater or less extent modified the native fauna and flora. Dr. John Murray, of the Challenger, has set a good example in this direction by sending a young official from the Natural History Museum to Christmas Island, in the Indian Ocean, one of the few untouched islands that remain, lying far away from any other land, to the southeast of the Keelings. What islands are to the ocean, lakes are to the land. It is only recently that these interesting geographical features have received the attention they deserve. Rivers are of not less geographical interest than lakes, and these have also recently been the subject of special investigation by physical geographers. But time does not admit of my going farther. I might have pointed out the wide and vastly interesting field presented by what the Germans call anthropogeography, dealing with the interrelations between humanity and its geographical environment. Geography, Mr. Mackinder has said, is the physical basis of history; it is, indeed, the physical basis of all human activity, and from that standpoint the field for geographical research is unbounded. But I can only hint at this. I have endeavored to indicate what are some of the leading geographical problems of the future, first in order to show at this somewhat critical epoch how very much yet remains to be done, how many important lines of inquiry are open to the geographical student.

[Continued from Supplement, No. 1132, page [illegible].]

ADDRESS BY SIR JOHN EVANS,

K.C.B., D.C.L., LL.D., Sc.D., Treas. R.S., V.P.S.A., For. Sec. G. S.; Correspondant de l'Institut de France, etc.; President of the British Association for the Advancement of Science.*

It must, moreover, be remembered that in what are probably the earliest of the palæolithic deposits of the eastern counties, those at the highest level, near Brandon, in Norfolk, where the gravels contain the largest proportion of pebbles derived from glacial beds, some of the implements themselves have been manufactured from materials not native to the spot but brought from a distance, and derived in all probability either from the bowlder clay or from some of the beds associated with it.

We must, however, take a wider view of the whole question, for it must not for a moment be supposed that there are the slightest grounds for believing that the civilization, such as it was, of the palæolithic period originated in the British Isles. We find in other countries implements so identical in form and character with British specimens that they might have been manufactured by the same hands. These occur over large areas in France under similar conditions to those that prevail in England. The same forms have been discovered in the ancient river gravels of Italy, Spain, and Portugal. Some few have been recorded from the north of Africa, and analogous types occur in considerable numbers in the south of that continent. On the banks of the Nile, many hundreds of feet above its present level, implements of the European types have been discovered; while in Somaliland, in an ancient river valley at a great elevation above the sea, Mr. Seton-Karr has collected a large number of implements formed of flint and quartzite, which, judging from their form and character, might have been dug out of the drift deposits of the Somme or the Seine, the Thames or the ancient Solent.

In the valley of the Euphrates implements of the same kind have also been found, and again farther east in the lateritic deposits of southern India they have been obtained in considerable numbers. It is not a little remarkable, and is at the same time highly suggestive, that a form of implement almost peculiar to Madras reappears among implements from the very ancient gravels of the manzanares at Madrid. In the case of the African discoveries we have as yet no definite palæontological evidence by which to fix their antiquity, but in the Narbadá valley of western India palæolithic implements of quartzite seem to be associated with a local fauna of Pleistocene age, comprising, like that of Europe, the elephant, hippopotamus, ox, and other mammals of species now extinct. A correlation of the two faunas with a view of ascertaining their chronological relations is beset with many difficulties, but there seems reason for accepting this Indian Pleistocene fauna as in some degree more ancient than the European.

Is this not a case in which the imagination may be fairly invoked in aid of science? May we not from these data attempt in some degree to build up and reconstruct the early history of the human family? There, in eastern Asia, in a tropical climate, with the means of subsistence readily at hand, may we not picture to ourselves our earliest ancestors gradually developing from a lowly origin, acquiring a taste for hunting, if not indeed being driven to protect themselves from the beasts around them, and evolving the more complicated forms of tools or weapons from the simpler flakes which had previously served them as knives? May we not imagine that, when once the stage of civilization denoted by these palæolithic implements had been reached, the game for the hunter became scarcer, and that his life in consequence assumed a more nomad character? Then, and possibly not till then, may a series of migrations to "fresh woods and pastures new" not unnaturally have ensued, and these following the usual course of "westward toward the setting sun," might eventually lead to a palæolithic population finding its way to the extreme borders of western Europe, where we find such numerous traces of its presence.

How long a term of years may be involved in such a migration it is impossible to say, but that such a migration took place the phenomena seem to justify us in believing. It can hardly be supposed that the process that I have shadowed forth was reversed, and that man, having originated in northwestern Europe, in a cold climate where clothing was necessary and food scarce, subsequently migrated eastward to India and southward to the Cape of Good Hope! As yet, our records of discoveries in India and Eastern Asia are but scanty; but it is there that the traces of the cradle of the human race are, in my opinion, to be sought, and possibly future discoveries may place upon a more solid foundation the visionary structure that I have ventured to erect.

It may be thought that my hypothesis does not do justice to what Sir Thomas Browne has so happily termed "that great antiquity, America." I am, however, not here immediately concerned with the important neolithic remains of all kinds with which this great continent abounds. I am now confining myself to the question of palæolithic man and his origin, and in considering it I am not unmindful of the Trenton implements, though I must content myself by saying that the "turtleback" form is essentially different from the majority of those on the wide dissemination of which I have been speculating, and, moreover, as many here present are aware, the circumstances of the finding of these American implements are still under discussion.

Leaving them out of the question for the present, it may be thought worth while to carry our speculations rather further, and to consider the relations in time between the palæolithic and the neolithic periods. We have seen that the stage in human civilization denoted by the use of the ordinary forms of palæolithic implements must have extended over a vast period of time if we have to allow for the migration of the primeval hunters from their original home, wherever it may have been in Asia or Africa, to the west of Europe, including Britain. We have seen that, during this migration, the forms of the weapons and tools made from silicious stones had become, as it were, stereotyped, and further that, during the subsequent extended period implied by the erosion of the valleys, the modifications in the form of the implements and the changes in the fauna associated with the men who used them were but slight.

At the close of the period during which the valleys were being eroded comes that represented by the latest occupation of the caves by palæolithic man, when both in Britain and in the south of France the reindeer was abundant; but among the stone weapons and implements of that long troglodytic phase of man's history not a single example with the edge sharpened by grinding has as yet been found. All that can safely be said is that the larger implements as well as the larger mammals had become scarcer, that greater power in chipping flint had been attained, that the art of the engraver and the sculptor had considerably developed, and that the use of the bow had probably been discovered.

Directly we encounter the relics of the neolithic period, often, in the case of the caves lately mentioned, separated from the earlier remains by a thick layer of underlying stalagmite, we find flint hatchets polished at the edge and on the surface, cutting at the broad and not at the narrow end, and other forms of implements associated with a fauna in all essential respects identical with that of the present day.

Were the makers of these polished weapons the direct descendants of palæolithic ancestors whose occupation of the country was continuous from the days of the old river gravels? or had these long since died out, so that after western Europe had for ages remained uninhabited, it was repeopled in neolithic times by the immigration of some new race of men? Was there in fact a "great gulf fixed" between the two occupations? or was there in Europe a gradual transition from the one stage of culture to the other?

It has been said that "what song the Sirens sang, or what name Achilles assumed when he hid himself among women, though puzzling questions, are not beyond all conjecture;" and though the questions now proposed may come under the same category, and must await the discovery of many more essential facts before they receive definite and satisfactory answers, we may, I think, throw some light upon them if we venture to take a few steps upon the seductive, if insecure, paths of conjecture. So far as I know, we have as yet no trustworthy evidence of any transition from the one age to the other, and the gulf between them remains practically unbridged. We can, indeed, hardly name the part of the world in which to seek for the cradle of neolithic civilization, though we know that traces of what appear to have been a stone-using people have been discovered in Egypt, and that what must be among the latest of the relics of their industry have been assigned to a date some 3,500 to 4,000 years before our era. The men of that time had attained to the highest degree of skill in working flint that has ever been reached. Their beautifully made knives and spearheads seem indicative of a culminating point reached after long ages of experience; but whence these artists in flint came or who they were is at present absolutely unknown, and their handiworks afford no clew to help us in tracing their origin.

Taking a wider survey, we may say that, generally speaking, not only the fauna but the surface configuration of the country were, in western Europe at all events, much the same at the commencement of the neolithic period as they are at the present day. We have, too, no geological indications to aid us in forming any chronological scale.

The occupation of some of the caves in the south of France seems to have been carried on after the erosion of the neighboring river valleys had ceased, and so far as our knowledge goes these caves offer evidence of being the latest in time of those occupied by man during the palæolithic period. It seems barely possible that though in the north of Europe there are no distinct signs of such late occupation, yet that, in the south,

* Delivered at Toronto, August 18, 1897.

man may have lived on, though in diminished numbers; and that in some of the caves, such, for instance, as those in the neighborhood of Mentone, there may be traces of his existence during the transitional period that connects the paleolithic and neolithic ages. If this were really the case, we might expect to find some traces of a dissemination of neolithic culture from a north Italian center, but I much doubt whether any such traces actually exist.

If it had been in that part of the world that the transition took place, how are we to account for the abundance of polished stone hatchets found in Central India? Did neolithic man return eastward by the same route as that by which in remote ages his paleolithic predecessor had migrated westward? Would it not be in defiance of all probability to answer such a question in the affirmative? We have, it must be confessed, nothing of a substantial character to guide us in these speculations; but, pending the advent of evidence to the contrary, we may, I think, provisionally adopt the view that, owing to failure of food, climatal changes, or other causes, the occupation of western Europe by paleolithic man absolutely ceased, and that it was not until after an interval of long duration that Europe was repeopled by a race of men immigrating from some other part of the globe where the human race had survived, and in course of ages had developed a higher stage of culture than that of paleolithic man.

I have been carried away by the liberty allowed for conjecture into the regions of pure imagination, and must now return to the realms of fact, and one fact on which I desire for a short time to insist is that of the existence at the present day, in close juxtaposition with our own civilization, of races of men who, at all events but a few generations ago, lived under much the same conditions as did our own neolithic predecessors in Europe.

The manners and customs of these primitive tribes and peoples are changing day by day, their languages are becoming obsolete, their myths and traditions are dying out, their ancient processes of manufacture are falling into oblivion, and their numbers are rapidly diminishing, so that it seems inevitable that ere long many of these interesting populations will become absolutely extinct. The admirable Bureau of Ethnology instituted by our neighbors in the United States of America has done much toward preserving a knowledge of the various native races in this vast continent; and here in Canada the annual Archeological Reports presented to the minister of education are rendering good service in the same cause.

Moreover, the committee of this association appointed to investigate the physical characters, languages, and industrial and social conditions of the northwestern tribes of the Dominion of Canada is about to present its twelfth and final report, which, in conjunction with those already presented, will do much toward preserving a knowledge of the habits and languages of those tribes. It is sad to think that Mr. Horatio Hale, whose comprehensive grasp of the bearings of ethnological questions, and whose unremitting labors have so materially conduced to the success of the committee, should be no longer among us. Although this report is said to be final, it is to be hoped that the committee may be able to indicate lines upon which future work in the direction of ethnological and archeological research may be profitably carried on in this part of Her Majesty's dominions.

It is, however, lamentable to notice how little is being or has been officially done toward preserving a full record of the habits, beliefs, arts, myths, languages and physical characteristics of the countless other tribes and nations more or less uncivilized which are comprised within the limits of the British Empire. At the meeting of this association held last year at Liverpool it was resolved by the general committee "that it is of urgent importance to press upon the government the necessity of establishing a bureau of ethnology for Greater Britain, which, by collecting information with regard to the native races within and on the borders of the empire, will prove of immense value to science and to the government itself." It has been suggested that such a bureau might, with the greatest advantage and with the least outlay and permanent expense, be connected either with the British Museum or with the Imperial Institute, and the project has already been submitted for the consideration of the trustees of the former establishment.

The existence of an almost unrivaled ethnological collection in the museum, and the presence there of officers already well versed in ethnological research, seem to afford an argument in favor of the proposed bureau being connected with it. On the other hand, the Imperial Institute was founded with an especial view to its being a center around which every interest connected with the dependencies of the empire might gather for information and support. The establishment within the last twelve months of a scientific department within the institute, with well appointed laboratories and a highly trained staff, shows how ready are those concerned in its management to undertake any duties that may conduce to the welfare of the outlying parts of the British Empire; a fact of which I believe that Canada is fully aware. The institute is therefore likely to develop, so far as its scientific department is concerned, into a bureau of advice in all matters scientific and technical, and certainly a bureau of ethnology such as that suggested would not be out of place within its walls.

Wherever such an institution is to be established, the question of its existence must of necessity rest with Her Majesty's government and treasury, inasmuch as without funds, however moderate, the undertaking cannot be carried on. I trust that in considering the question it will always be borne in mind that in the relations between civilized and uncivilized nations and races it is of the first importance that the prejudices and especially the religious or semireligious and caste prejudices of the latter should be thoroughly well known to the former. If but a single "little war" could be avoided in consequence of the knowledge acquired and stored up by the Bureau of Ethnology preventing such a misunderstanding as might culminate in warfare, the cost of such an institution would quickly be saved.

I fear that it will be thought that I have dwelt too long on primeval man and his modern representatives, and that I should have taken this opportunity to discuss some more general subject, such as the advances made in the various departments of science since last this association met in Canada. Such a subject would no doubt have afforded an infinity of interesting topics on which to dilate. Spectrum analysis, the origin and nature of celestial bodies, photography, the connection between heat, light, and electricity, the practical applications of this latter, terrestrial magnetism, the liquefaction and solidification of gases, the behavior of elements and compounds under the influence of extreme cold, the nature and uses of the Roentgen rays, the advances in bacteriology and in prophylactic medicine, might all have been passed under review, and to many of my audience would have seemed to possess greater claims to attention than the subject that I have chosen.

It must, however, be borne in mind that most, if not indeed all, of these topics will be discussed by more competent authorities in the various sections of the association by means of the presidential addresses or otherwise. Nor must it be forgotten that I occupy this position as a representative of archeology, and am therefore justified in bringing before you a subject in which every member of every race of mankind ought to be interested—the antiquity of the human family and the scenes of its infancy.

Others will direct our thoughts in other directions, but the farther we proceed the more clearly shall we realize the connection and interdependence of all departments of science. Year after year, as meetings of this association take place, we may also foresee that "many shall run to and fro and knowledge shall be increased." Year after year advances will be made in science, and in reading that book of nature that lies ever open before our eyes, successive stones will be brought for building up that temple of knowledge of which our fathers and we have labored to lay the foundations. May we not well exclaim with old Robert Recorde?

"Oh woorthy temple of Goddes magnificence: Oh throne of glorye and seate of the lorde: thy substance most pure what tonge can describe? thy signes are so wonderous, surmountinge mannes witte, the effects of thy motions so divers in kinde: so harde for to searche, and worse for to fynde—Thy woorkes are all wonderous, thy cunning unknowen: yet seedes of all knowledge in that booke are sowen—And yet in that boke who rightly can reade, to all secrete knowledge it will him straighte leade."*

PROF. MAYER.

ALFRED MARSHALL MAYER.†

A MAN of science, whose work was unique in the domain which he had selected, and who will long be held in warm remembrance by a large circle of friends, has lately passed away.

In 1784 there emigrated to America a young German, Christian Mayer, a member of an ancient family in the city of Ulm, in Württemberg. He made his home in Baltimore, where, by strong intelligence and well directed industry, he amassed a fortune. To his two sons, Charles F. and Brantz, he gave the best educational advantages of the day. The former became a prominent lawyer, well known in the best social circles of Baltimore on account of his refinement and broad literary culture, while the latter traveled and wrote extensively, his historical work, especially in connection with Mexico, being of high authority and acknowledged value.

On the 13th day of November, 1836, a son was born to Charles F. Mayer. At an early age the boy exhibited great mechanical ingenuity and a lively interest in the external world of nature. At St. Mary's College, in Baltimore, he was afforded all the usual facilities for an elementary liberal education, and especially for classical training; but this did not suit his native bent. At the age of sixteen years he gave up the school room, and the following two years were spent chiefly in the workshop and the draughting room of a mechanical engineer. Here was abundant opportunity for acquiring familiarity with the use of tools and developing manipulative skill. At the same time there was a continual stimulus to private study in connection with the daily application of the laws of physics and mechanics. This course of study in applied science was a natural precursor to the resumption of more systematic work, not in the class room, but in the laboratory. A course of chemistry was undertaken, and two years were spent largely in mastering the principles and processes of quantitative analysis. It was during these years of private study and practical work that young Mayer attracted the attention of a man whose personal influence was chiefly instrumental in determining the future direction of the student's energies. Joseph Henry was at this time secretary of the Smithsonian Institution, and for thirty years he had been identified with the advancement of pure science in America. Industrial science needs no advocates. Its importance is recognized by all. Its immediate connection with material progress and its quick response to commercial demands are sufficient to bring within the ranks of its devotees the great majority of those who undertake laboratory work with a definite purpose. Henry had never underrated the value or the need of industrial science, but he had emphasized the importance of investigation from the more unselfish standpoint of one who regarded intellectual acquisition as a priceless good in itself apart from all commercial recompense. He apprehended the brightness, the alertness, the originality of the Baltimore student, and accorded him that sympathetic recognition which constitutes the greatest stimulus that a young man can receive. The friendship of an acknowledged master makes a willing and easily directed pupil. Ideals of excellence are thus formed for life. Subsequent experience may sometimes modify these, but they are rarely ever discarded.

At the early age of twenty years Mayer was appointed to the chair of physics and chemistry in the University of Maryland. He had already, during the previous year, published his first contribution to science, the description of a "new apparatus for the determination of carbonic acid." This was soon republished in Germany.

His new duties absorbed now most of his time, but a second paper appeared in the American Journal of Science, in 1857, on the estimation of the weights of very small portions of matter. In this he showed that by the deflection of a fine glass fiber it is possible to estimate a variation in weight so small as the thousandth

* Preface to Robert Recorde's Castle of Knowledge, 1556.

† By Prof W. Le Conte Stevens, in Science. Prof. Stevens is particularly well adapted to write of his friend, owing to their mutual love for acoustics, in which branch of physics they have both done notable work. Prof. Mayer will be specially remembered by readers of the SCIENTIFIC AMERICAN SUPPLEMENT, by reason of his articles in 1877-1878 on "The Minute Measurements of Modern Science." The following is a synopsis of these articles, with the numbers of the papers: I, Size of the magnitudes to be measured, 56; II, Micrometer screw, 56; III, Measuring by means of micrometer screw with contact level, 60; IV, Spherometer, 62; V, Micrometer microscope, 64; VI, Compound microscope applied to minute measurements, 67; VII, Vernier and vernier microscope, 72; VIII, Cathetometer, 77; IX, Dividing engine, 80; X, Construction of a perfect screw, 92; XI, Rotating mirrors applied to the measurement of minute lengths, Saxton's comparator, 98; XII, XIII, XIV, Saxton's comparator, 100, 103, 107; XV, Horizontal pendulum, 112; XVI, Use of tuning fork, 161; XVII, Wheatstone's experiments to measure velocity of electricity, 165; XVIII, XIX, On nature and duration of electric discharge; Feddersen, Henry, Rood and Mayer's experiments, 166, 175; XX, Measurement of light waves, 177.

part of a milligramme. In 1859 he accepted a chair in Westminster College, Missouri, where two years were spent; but the equipment of this institution was insignificant and no original work was accomplished. The breaking out of the civil war determined his return to Baltimore, and in 1863 he went to Paris, where two years were occupied in special study, chiefly under the direction of Regnault. The influence of the great French physicist, and the general atmosphere of the University of Paris, strengthened the bias in favor of pure science which had been received in youth from Henry.

Soon after his return to America, in 1865, Prof. Mayer was called to the chair of physics and chemistry at Pennsylvania College, in Gettysburg, which he gave up in 1867 to accept that of physics and astronomy in Lehigh University. This in turn was renounced in 1871 for the purpose of joining in the upbuilding of the new Stevens Institute of Technology, at Hoboken, with which his connection continued up to the time of his death, July 13, 1897. It is with this institution, therefore, that his name will always be chiefly identified, though his researches were for the most part in channels somewhat removed from those that are usually characteristic of an engineering school. Its instrumental equipment was unusually good, and proximity to a great metropolis afforded the intellectual stimulus and the prompt recognition of merit which are wanting in isolated institutions of learning.

While connected with Lehigh University Prof. Mayer designed an astronomical observatory and superintended its construction. He erected the instruments and, without assistance, finished the tedious work of adjusting them. A series of observations on Jupiter followed, and its publication was reproduced in England. During the summer vacation of 1869 he was deputed by the United States government to take charge of a party of astronomers at Burlington, Iowa, where the solar eclipse of August 7 was observed. During the eclipse more than forty successful photographs were taken, each exposure lasting 0·002 second. Four of these were during the eighty-three seconds of totality. This was in the early days of instantaneous photography and was accounted an unusual feat. An abstract of the results of measurements on these photographs was published in the Journal of the Franklin Institute. In the same journal, about this time, he published a number of articles on physical and astrophysical subjects. At the Salem meeting of the Scientific Association, 1869, a paper was read "On the Thermodynamics of Waterfalls." At Trenton Falls and at Niagara Falls careful observations had been made on the temperature of the water at the top of the cataract and just beyond the point of impact at the bottom. The arrest of motion develops heat, and this was found to be manifested in a measurable rise of temperature, when the air was charged with moisture and not much warmer or colder than the water, the change being in accordance with calculation based on Joule's equivalent. But under other conditions this effect was masked to such an extent by the cooling effect of evaporation and conduction that there was sometimes a lower temperature at the bottom than at the top.

Soon after entering upon his duties at Hoboken, Prof. Mayer began the series of investigations in acoustics for which he is, perhaps, best known, and which made him decidedly the leading authority on this subject in America. In the first of his papers he showed how the co-vibration of two nearly unisonant tuning forks may be utilized to demonstrate Doppler's well known principle that wave length may be modified by translation of the vibrating body. This was soon followed by another paper in which he gave a method of detecting the phases of vibration in the air surrounding a sounding body. Two resonators responding to the pitch of the source were employed, each connected with a manometric capsule. One of these resonators being fixed and the other movable, the recurring changes in the compound flame image gave the means of measuring wave length directly in the vibrating air and exploring the form of the wave surface. A simple and precise method was developed from this for measuring wave lengths and velocities of sound in gases at various temperatures; and an acoustic pyrometer was devised by which furnace temperatures were capable of measurement with a degree of accuracy approaching that of the air thermometer. The same optical method of interference was then further applied to the determination of the relative intensities of sounds. The range of application of this method is somewhat limited, but within this range it is more precise than any other method devised for the same purpose. One application was to the measurement of the powers of various substances to transmit and to reflect sonorous vibrations. An investigation of the relative absorbing powers of different media for sound led to an approximate determination of the mechanical equivalent of an aërial sonorous vibration. The energy per second given forth in aërial vibrations by an Ut$_3$ fork (256 vd.), set in motion by intermittent electro-magnetic action and placed before an appropriate resonator, was found to be about one millionth of Joule's unit, or enough to raise one gramme through a height of ten centimeters. This result was accomplished by measuring the relative intensities of the sound given forth by the same fork, first when vibrating freely, then when the motion of its prongs was damped by the expenditure of part of its energy on India rubber. The rise of temperature of the rubber was measured by use of thermopile and galvanometer, and its specific heat determined by ordinary methods. The difficulties attendant upon such an experiment are very great, and no one but an experimentalist of exceptional skill and patience would be apt to undertake it.

These strictly physical investigations led Prof. Mayer into the domain of physiology in its bearing upon the phenomena of audition. The most important principle in acoustics is that of harmonic motion, simple and compound, as embodied in Fourier's theorem. Helmholtz was the first to apply this to the analysis of musical quality, and in doing so the subjective method of resonators was utilized with great skill. Prof. Mayer sought objective methods and devised several of these, the most striking of which was that of employing tense threads as media for the conveyance of energy from a vibrating membrane to mounted tuning forks adjusted in pitch to respond to the components of the compound sound under examination. Recognizing the capacity of the ear, when sufficiently trained, to accomplish this analysis to a considerable extent without instrumental aid, he sought to learn the mechanism of the auditory apparatus of some of the lower types of animal life. Some new and interesting facts were thus discovered in relation to the function of the antennæ of the mosquito in audition, and he showed how an insect may determine the direction of sounds by means of its antennæ. In this connection good reason was found for the belief that the terminal auditory nerve fibrils in the human ear vibrate just half as often in a given time as the membrane of the tympanum and the ossicles. This hypothesis partially accounts for the marked difference in quality when the same sound is successively heard, first directly through the open ear and then through the medium of the bony portions of the head.

Prof. Mayer's most important acoustic research was his determination of the law connecting the pitch of a sound with the duration of the residual sensation in the ear. An explanation of the method adopted cannot be here given without entering unduly into details. This law gave a quantitative character to results which Helmholtz had attained only qualitatively. It is of fundamental importance in its application to musical harmony. It explains why certain combinations of tones which are harmonious in the upper portions of the musical scale become rough and discordant in the lower portions. This mere fact the musical composer was long compelled to recognize, though hitherto it had been inexplicable. The labor involved in this work was great, and before its completion the investigator's power of audition in one ear was thereby permanently impaired. The first experiments were published in 1874; a redetermination was made in 1875, and again with improved apparatus in 1893. He received the assistance of the most accomplished musical experts, including Madame Seiler, who had been associated with Helmholtz for a somewhat similar purpose, and Dr. Rudolph Koenig, of Paris, whose training in the detection of musical beats is unrivaled. Dr. Koenig, in 1893, rendered important service in ascertaining the limitations of what may now be properly called "Mayer's Law." This law is expressed by an equation in which the duration of the residual sensation is given as a function of vibration frequency, and this equation is readily translated into a curve. Between the limits of 100 and 4,000 vibrations per second there is closer accordance between the results of calculation and observation than in the case of Fechner's law, or indeed any other physiological law for which the attempt has been made to express sensation mathematically. Between 200 and 2,000 vibrations, including the range most constantly resorted to in music, the accordance is satisfactory, even when measured by physical rather than physiological standards. Due recognition of these important contributions to acoustic theory have been made by Mr. Ellis in his translation of Helmholtz's "Tonempfindungen" and by Prof. Zahm in his recent book (1892) on "Sound and Music." Mr. Ellis gave a special lecture in London for the purpose of explaining these discoveries and their application to the principles of musical harmony.

It was natural for Prof. Mayer to apply acoustic methods in work primarily undertaken for other purposes. In 1876 he devised improvements in what is now generally known as the electrographic method for the measurement of the velocity of projectiles and the determination of pitch. He utilized the spark from an induction coil for the purpose of marking seconds upon the sinuous trace of a tuning fork on smoked paper, and attained results of great accuracy. He studied with care the laws of vibration of tuning forks, and was the first to give accurately the correction to be applied in all such determinations on account of variation in temperature of the fork. Between 1889 and 1894 he conducted an elaborate research on the variation of the modulus of elasticity of various materials with change of temperature, as indicated by the transverse vibration of bars. From the observed pitch the velocity of propagation of sound in the bar is found, and this gives the modulus of elasticity. For the accurate determination of pitch it was necessary to visit Paris, where access was had to Dr. Koenig's grand tonometer, and where this accomplished acoustician freely gave his time and skill in furtherance of the work. The remarkable regularity in the results shows that this acoustic method, as conducted, is worthy of the greatest reliance. Among the materials thus studied was aluminum. Its modulus was found to be subject to large variation, and in every respect it is far inferior to steel for acoustic purposes.

(To be continued.)

ROSA WICHURAIANA.

THERE are very few of the wild types of Rosa whose flowering time comes so late in the year as the end of July and the beginning of August, but of those few R. Wichuraiana is one. It is of very recent introduction, but the distinct character of its growth and the late date at which it blossoms have already obtained for it considerable notice in this country, although not so much as in the United States, where it is already a popular shrub. It is a native of Japan, and reached this country by the way of the United States about five or six years ago. The two characters which more than any others distinguish this rose are its procumbent habit and the very lustrous dark green color of its leaves, these being, indeed, so bright on both sides

ROSA WICHURAIANA, HARDY ROSE—FLOWERS WHITE.

as to suggest their being coated with varnish. Each one consists of five, seven or nine leaflets, which are oblong or elliptical, serrated, and from ½ to 1 inch long. The petiole bears a few short spines and bristles, and the stipules have their margins set with glandular teeth. On the strong, succulent, non-flowering shoots of the current year the wood is armed with stout curved spines, but on the thinner flowering shoots of the following year they are mostly arranged in pairs just beneath each node. The flowers are of the purest white, and the clusters appear just above the dense carpet of glossy leaves, which completely covers the soil. Each flower is upward of two inches in diameter, the petals (normally five) often numbering six or seven under cultivation. This species should be given a rich soil, and, what is of equal or greater importance, the sunniest possible position. It is, no doubt, the intense and prolonged sunshine it receives in North America that causes it to flower so abundantly there. It is a plant of vigorous and luxuriant growth, and can be increased with the greatest ease by means of cuttings put in during the next two or three weeks.—The Gardeners' Chronicle.

A kerosene incandescent burner is made which will fit on an ordinary kerosene lamp. The kerosene is drawn up into a small chamber by a number of wicks, and is there vaporized by a small external flame. After two and one-half minutes the heat in this little chamber is sufficient to supply the vapor for a flame which raises the mantle to white heat. The mantle is similar to that used with a coal gas flame. A great drawback about this burner is that two and one-half minutes must elapse after the first application of light till the lamp is ready for use. A similar burner is made to use with a methylated spirits flame.—Uhland's Wochenschrift.

ENGINEERING NOTES.

Paris (France) is to be supplied with well water from the departments of the Eure and Loire, some 490 ft. above the level of Paris and over 100 miles away.—Zeitschrift für Architectur.

Cork paving has been tested in England, and is found to be very noiseless, elastic and waterproof. It gives a good hold to the feet, is never slippery, and withstands the action of the weather very well. The wear due to friction is also very small.—Monatschrift für den Oeffentlichen Baudienst.

A plan for connecting South and West Australia by railroad is under consideration. The distance between the ends of their railroad systems is only 553 miles, but the country to be traversed is an arid desert, and reservoirs must be built at twenty-five mile intervals along the whole line. The cost will be about $10,000,000.

The strongest steel ropes ever made are probably the two recently finished, says Uhland's Wochenschrift, by Messrs. Felten and Guilleaume, Mülheim, Germany, for a bridge over the Argen River, near the Boden Lake. These ropes are made of 259 wires, each about a quarter of an inch thick. They weigh some 135 lb. per yard, and their strength is such that it would require a force of 1,800,000 lb. weight to tear them. The bridge for which they are made will be 102 ft. long.

The Theatre Francais, at Paris, has a peculiar device to insure the greatest possible safety for the audience. Not only can the scene be separated from the audience by a hermetically closing steel curtain, but the roof of the scene can be uncovered at a moment's notice, so that a draught of air is produced which carries away the smoke and noxious gases produced in the fire. These, it is said, constitute the greatest danger to the audience, often rendering escape quite impossible. It is on the scene that the fire usually breaks out.—Monatschrift für den Oeffentlichen Baudienst.

Very few know it, but it is a fact, says the Washington Star, that the Pension Office Building is the largest brick building in the world. It has been subjected to much criticism, but it can stand it, for as time passes along there are many things seen about it that escaped notice when it was newer. In all there are over 10,000,000 bricks in the building. General Meigs took liberties with bricks that no other architect had ever attempted. He not only used bricks exclusively for the building, but he used them in constructing the stairs throughout the building. In the matter of stair building bricks have often been used for the riser, but the step has always been of iron, wood, slate or stone. In the Pension Office both riser and step are of brick. As a brick building, therefore, pure and simple, it is unique in construction, outside of the fact that it is the largest exclusively brick building in the world.

Some curious effects of the tests of the new magazine rifles in actual service are noted in Engineering. Cordite was accused of causing rapid wear of the rifling, and this charge must have had some foundation, as the Metford rifling has been abandoned in the weapons now issued, and has been replaced by the system devised by Rigby, which is said to wear well and give more accurate shooting than the Mannlicher, Mauser or Lebel systems. Certainly the wear cannot now be a very serious matter, if the reports can be relied on that accurate shooting has been made even after firing some thousands of rounds and the weapon is still serviceable after 8,000 or 9,000 rounds have been fired. In the Tochi punitive expedition the new Dumdum bullet will be employed, that originally used having proved deficient in stopping power. In the Chitral campaign one man was six times shot, and nevertheless he recovered. The private soldiers are, accordingly, losing confidence in the weapon.

The Railroad Gazette says: "The people of George Stephenson's race have not kept railroads to themselves, but so far they have a long lead of the rest of the world in constructing them. There is not much room in Great Britain for a great mileage, and in Europe, of the total 155,284 miles, only 20,977 miles are on British territory. But of the 26,890 miles in Asia, 19,700 miles are on such territory; in Africa, 2,845 miles out of 8,169; in America, of the 48,005 miles outside of the United States, 16,719 miles are British, and of course, all the 13,888 miles in Australia. Altogether, there are 74,129 miles of railroad in the British possessions, which added to the 181,717 miles in the United States (all the figures are for 1895), makes the considerable figure of 255,846 miles, which is nearly three-fifths of the railroads of the world. And this takes no account of 7,127 miles of Mexican railroad, all built with American and English capital and skill, and nearly all with their materials, nor of the countless lines built elsewhere in the four quarters of the globe with English money and skill, and mostly with English iron and machinery. We seem to be pre-eminently the railroad race."

The successful beginning of the work at the new basic open-hearth steel plant in Birmingham, Ala., calls attention to the possible entrance of the South into the steel market, says the Engineering and Mining Journal. The output of that section in the past has been so closely limited to pig iron that it has not been considered at all as a competitor in steel or any finished products of steel. Of course the production is for the present so limited that it will hardly supply the needs of the Birmingham rolling mill; but there is little doubt that it can and will be increased considerably in the future. There does not seem to be any probability of the establishment of a new rail mill in the South; but a considerable trade in beams, girders and structural iron for Southern cities could be built up, and a mill at Birmingham could readily compete with the Pennsylvania works at all the cities along the Ohio, and would have a considerable advantage over them in any town on or west of the Mississippi below Cairo. It is, moreover, a question still, whether with the present low costs, both of material and labor, it would not be possible for Southern steel works to furnish billets at a price which would enable them to take at least part of the trade of those Eastern mills which work on purchased billets. It is quite possible, also, that a trade in billets and tin plate bars for export might be built up, while there are possibilities in wire rods also. As long as costs are kept down to the present limit, there will be no trouble in finding a market for Southern steel.

ELECTRICAL NOTES.

In London, England, electric propulsion is shortly to be substituted for horse traction. The lines are owned by the town, but are to be let out to companies as soon as the alterations are complete.—Uhland's Wochenschrift.

The number of persons carried by the electric cars at the Berlin Industrial Exhibition (Germany) reached its maximum on August 29, when 35,800 persons traveled on the lines, and was smallest on the 19th of May, when only 4,700 fares were taken.—Zeitschrift für Architectur.

The number of lamps supplied with the electric current in Paris (France) at the end of October, 1896, was 545,914, in London (England) 1,178,000. The current used in Paris amounted to 8,107,253 kilowatt hours, in London about 19,000,000 kilowatt hours. In Paris the price of 1 kilowatt hour is 25 cents, in London about half as much.—Zeitschrift für Architectur.

The electric lighting of railway cars is constantly coming more in use in Switzerland. The number of cars lit by electricity at the end of the year 1896 was 525. On the Jura-Simplon line electric lighting will be introduced throughout by the end of the current year. The Swiss Central Railroad has furnished all its new wagons with electric lighting appliances for the last two years. The Northeast Railroad has ordered 65 wagons, which are to be lighted by electricity. Many smaller lines, too, have followed the general motion.—Monatschrift für den Oeffentlichen Baudienst.

The municipal council of Berlin, Germany, has decided, by 58 votes against 24, that the horse cars in the German capital shall be replaced by a tramway propelled by electricity. Among the resolutions passed are the following: The right of other companies to use the tracks was restricted to a certain three sections, and 410 yards. The company shall not keep a man at work more than ten hours in succession, except in special, rare cases. Season tickets are to be issued for any line, not as heretofore for any two lines. The cars are expected to make their first trip in October.—Uhland's Wochenschrift.

A practical electrical plowing installation has been put down in France by M. Felix Prat, in the department of Tarn, says The Engineer. The power is derived from a turbine working a dynamo, the current from which is distributed to different points on the estate by four overhead lines, with copper conductors, in the form of a cable. Two of these lines are 1800 and the remaining two 1600 meters in length. These lines, wherever possible, are supported on trees—strong poplars—in order to economize posts, while securing rigid supports. The plow is drawn by a simple windlass worked by the dynamo, and can be worked to a distance of 450 meters on each side of the cable line.

A number of electrical cabs, belonging to the London Electrical Cab Company, have commenced to ply for hire in the streets of London at the same fares as are charged for the horse vehicles they are designed to supplant. In shape these cabs, which carry two persons, resemble coupes; they run on four rubber tired wheels, are comfortably upholstered in leather, and possess the luxuries of spring cushions and electric light. The driver, who sits in front, has at his right hand a small steering wheel which acts on the front pair of wheels, and at his left a single lever which regulates the speed. By means of a foot lever the driver can apply the brake and at the same time cut off the current from the motor.

The transmission of power by electricity is, in some cases, retarded in coal pits because of their fiery nature, which renders it imperative that no sparking shall ever take place where it could ignite a fiery mixture of air and gas. With direct current motors it has therefore been necessary to completely box in the commutator and brushes, which renders them rather inaccessible. The great advantages of a three-phase or a two-phase alternate current system for such work cannot be too largely brought to the notice of the public, says the Electrical Engineer. When motors of the above type and of reasonable output are used, a simple throw-on switch is all that is required in the way of regulating gear, and the contacts of this switch are the only points at which sparking can occur. It is a comparatively easy task to box in this switch gear. The motors being without commutators or collecting rings, are absolutely free from sparking. The cables leading to the motors only need protection, and there is no lack on the market of well protected concentrics which will give safety in this direction. The motors have a good starting torque, and can be relied on to drive coal cutting machinery and hauling ropes. We must admit, however, that up to the present we have not seen a satisfactory arrangement for an electric locomotive to be worked in fiery pits.

Anybody who has had much to do with books knows that it is no easy task to keep them dusted, and extremists, in view of the difficulty, have gone so far as to assert that you should never dust books, says the Electrical Engineer. They should be left undisturbed till needed, and then the rust and dust of ages can be taken off with a napkin. This, however, is regarded as the heresy of sheer laziness, and the practical suggestion is now made that the fan motor is the thing wherewith to banish grime and dust from a well kept library. All that is necessary is to turn the breeze loose over the shelves, with the windows open, and in a few minutes the tops and covers will show up in all their pristine freshness. Obviously the fans can be portable, and either carried around in the hand by a long flexible cord or hitched up at suitable plugs and left spinning. Thus dust will not be able to settle for long and will rarely have a chance to accumulate even for a single day. Electricity has, therefore, another claim to use in libraries. Gas is well known to have a deleterious effect on books, and Mr. Blades, the well known bibliographer, once said there was nothing to equal it for rotting covers, even those of leather. With electricity, a public or private library will be better lighted and better kept, while it will also be safely available more hours of each day.

MISCELLANEOUS NOTES.

Vegetable ivory may be distinguished from real, animal ivory by applying a little sulphuric acid (concentrated) to the surface of the doubtful material. After some ten to fifteen minutes the vegetable product shows a pink coloration, which may be washed off with water, while true ivory remains unchanged.—La Science en Famille.

An improved composing box for type, with a wire net bottom, has recently been patented. The wire netting is made fine or coarse, according to the type it is intended for. Under the netting a wooden bottom can be slid in like a lid. The object of the invention is to facilitate the cleaning of the box, in which dust from wearing types collects.—Uhland's Wochenschrift.

The use of gas for heating purposes, particularly for large buildings and schools, is recommended on several grounds. The easy and quick regulation of the heat given results in considerable saving, and since radiating heat is employed, a quick rise of temperature is produced. The cost of installation and keeping in repair is small. Ample ventilation is afforded through the fireplaces, the air is not deteriorated by the fire and there is no danger of explosion.—Zeitschrift für Architectur.

A process by which not only the iron but also the phosphorus may be saved from iron ores containing phosphorus was recently patented. The ores are mixed with coal, the mixture is raised to a dull red heat, and steam is led over it. Water gas is formed, which acts as a reducing agent on the iron at a temperature when the phosphorus is left unaffected. The phosphorus then remains for later treatment.—Wiener Gewerbe Zeitung.

Spices are often adulterated with the residues of similar spices, from which, however, the essence has been extracted. Thus pepper has been found to contain some forty per cent of ginger residues. Ginger itself is often only one-half aromatic, the remainder being tasteless residue. Pepper is often adulterated with ground up pepper stems. Even unground pepper is forged, ordinary white grains being colored black and sold as Singapore pepper.—Uhland's Wochenschrift.

A new device for closing tins of preserves, etc., which was recently patented in Germany, has many advantages. The process of preparing the tinned products is carried on in vacuo, much time and heat being thereby saved, since many of the preserves have to be boiled. At the same time the vacuum is taken advantage of for closing the tins. The lid is applied, after a washer has been interposed, and then the tin is taken out into the air under atmospheric pressure. To open the tin, all that is required is to bore a hole in the lid.—Wiener Gewerbe Zeitung.

Roof tiles are made in Warsowi, Russia, of thin wood sheets, which are glued on one another so that the grain of the wood is crossed. A thin, elastic plate of wood is thus obtained, which cannot by any accident be twisted out of shape. These tiles resist the action of the weather very well, after they have received an application of pitch; they will even stand boiling in water for several hours. The weight of a roofing of these tiles is 12 pounds per square yard. They can be rendered fireproof by saturation with potassium silicate (soluble glass).—Monatschrift für den Oeffentlichen Baudienst.

The ambitious scheme of the Nippon Yusen Kaisha—the Japan Steamship Company—to compete with existing lines to Europe, America and Australia has been the reverse of successful, so far as the experience of six months' working is concerned, says The Engineer. The expenditure during that period was 4,968,365 yen, inclusive of 683,145 yen for depreciation and insurance and repair reserves, while the receipts totaled 4,805,048 yen, inclusive of 440,000 yen as government subsidy and 217,093 yen in respect of navigation bounties. This shows a loss on the half year of 163,336 yen, despite which the directors declared a dividend of 10 per cent., absorbing 605,000 yen, a feat accomplished by utilizing the whole of the "dividends equalization fund," amounting to 427,561 yen, and the balance of 190,539 yen brought forward from the previous account. This reduces the available funds to 2,561 yen, which sum is to be carried forward. The Syren observes from the report that the directors look for better things in the immediate future, but the opinion of those most competent to judge is that they will look in vain, unless the directors revert to the old state of things and discontinue these long distance voyages.

The Washington Star says: "Over 20,000,000 packages of vegetable, flower and field seed have been distributed by the Department of Agriculture during the past spring. This distribution has given to each member of Congress 40,000 packages of seed, at a total cost of $130,000. Over 1,000,000 of these packages were flower seed, and nearly 300,000 field seed, the balance being a great variety of vegetables. In the entire distribution nearly every variety of vegetable known to the agriculturists was distributed. There were 32 varieties of beans, 10 varieties of beets, 23 varieties of cabbage, 11 varieties of carrots, 19 varieties of sweet corn, 18 kinds of cucumbers, 30 kinds of lettuce, 19 varieties of muskmelons, 17 kinds of watermelons and 15 varieties of onions. The entire amount of seeds distributed was sufficient to plant an area of 355 square miles, or about six times the size of the District of Columbia. This is the largest distribution of seed ever attempted by the Department of Agriculture, and it is said that seedsmen all over the country are complaining that they do not make sales to farmers and others because they are getting all the seed they want free from the Department of Agriculture. The distribution of seed in 1893 amounted to 8,900 packages for each member of Congress, at a total cost of $66,548; in 1894 each Congressman got 16,000 packages, the entire cost to the government being $57,000; in 1895 the number of packages of seeds distributed was the same as in the previous year, but the total cost was reduced to $47,000. In 1896 Congressmen got 15,000 packages each, and the government paid $80,500 for the whole lot. During the past spring each member of Congress has received 40,000 packages of seeds, for which the government has paid $130,000."

DR. MOUNT BLEYER'S TREATMENT FOR CONSUMPTION BY ELECTRICITY.

On the application of the principles underlying these experiments in the sterilization of lung tissue in tuberculosis.

The primary action of the galvanic current—It increases the amount of ozone in the blood, as shown by chemical test of the blood in the arteries—With my theory of animal electricity.*

By J. MOUNT BLEYER, M.D., F.R.A.M.S., LL.D., New York City.

PRELIMINARY TESTS.

FOR a period of seventy-two hours before entering upon the examinations, we hung in various portions of my laboratory slips of specially prepared paper saturated with a solution of iodide of starch and others moistened with tincture of guaiac. These, we all know, are acknowledged tests upon ozone. We kept the papers under careful observation, examining in strong light at intervals of an hour, and as there was no evidence of a reaction at the end of the allotted time we were justified in concluding that the atmosphere of the laboratory was free from ozone and the other gases which act upon starch and guaiac. Next we directed our attention to nitrous compounds in the air, for the reason that they, if they exist in the slightest appreciable quantity, give us a reaction very much like that of ozone, and their presence must be excluded in order to give any sensitive test for ozone practical chemical value.

The test we applied for nitrous compounds is an extremely useful one, unusually sensitive, and we give its chemistry for the benefit of those who may desire to repeat our experiments. It is named Gries' test after its discoverer. He observed that in sulphanilic acid and naphthylamine we have a reagent which acts on nitrous acid, but not on H_2O_2 or O_3. This discovery Gries made while engaged in studying the action of diazo-benzene sulphonic acid on naphthylamine.

He obtained his diazo-benzene sulphonic acid by heating sulphanilic acid with nitrous acid and calls attention to the extreme delicacy of the reaction, minute traces of nitrous acid sufficing to produce a dark red color in the presence of dilute sulphuric acid. The colored substance formed is an amido-azo derivative of the formula

$$C_6H_4(SO_3H)N = NC_{10}H_6NH_2 \dagger$$

called azo-amido-naphthalene-benzene-sulphonic acid. Prof. Slosvay ‡ of the Polytechnic school at Buda-Pesth increases the sensitiveness of the reaction by substituting acetic for sulphuric acid, and he can detect with it nitrous acid in aqueous solution in a dilution of one part nitrous acid to one thousand million parts of water.

The formula of the test is:

$$\underbrace{C_6H_4NH_2(SO_3H)}_{\text{Sulphanilic acid}} + \underbrace{C_{10}H_7NH_2}_{\text{Naphthylamine}} + HNO_2 =$$

$$C_6H_4(SO_3H)N = NC_{10}H_6NH_2$$

We availed ourselves of Slosvay's modification of Gries' formula.

A tank of a capacity of fifty gallons at a pressure of thirty pounds was filled with air from the laboratory. The air was sent through an air meter which registered one liter per minute and from this into a test tube containing distilled water through which it was allowed to bubble for ten minutes and then tested.

There was no immediate reaction, and only after half an hour's standing did we observe a tinge of color, so faint, however, as to be almost imperceptible in ordinary light. In order to see it we were obliged to back the test tube with pure white filter paper and hold it in the sunlight.

In view of the delicacy of Slosvay's reaction it was fair to assume that the quantity of nitrous acid in the air was so infinitesimally small that for practical purposes it could have no effect in interfering with the subsequent tests for ozone.

Ten liters of oxygen were treated in the same manner. The oxygen was first subjected to two washings in distilled water without giving any reaction to the nitrous acid test. The remaining forty gallons which were afterward liberated in the laboratory were washed in caustic soda and dried with sulphuric acid (c. p.) and bubbled through distilled water. There was no reaction with Gries' test, thus showing that the gas was absolutely pure and free from admixture with nitrous and other gases.

This concluded the preliminary testing. The object of the careful analyzing of the air of the laboratory, as you may already divine, was to devise means of testing for ozone in the open, and so avoid the less satisfactory method used by Schmitt, who treated his ozone in a balloon from which the oxygen had been removed as nearly as possible to do so by means of carbon dioxide, or handling it in a similar glass receiver from which all air had been exhausted, which was the manner in which Kühne conducted his experiments.

For several days work was suspended, and resumed again Monday, August 21, 1892. On that morning we were treated to a genuine surprise that caused me to ponder for awhile; and Dr. J. C. Dittrich, who, perhaps, ranks first among the authorities on ozone in this country, and who kindly assisted me in the chemical portion of my work, prepared several specially sensitive test papers, which on being moistened with distilled water, at once gave a reaction. The air of the laboratory was evidently charged with ozone, and we were at a loss to account for its presence. Speculation was soon set at rest when we recalled the violent thunder storms of the Sunday and Saturday before.

The ozone was the result of the intense static discharges of those days, and the amount that had been generated by the great Pluvius certainly was enormous and beyond measure; for that day and the three succeeding ones work had to be deferred, with all the preliminary testing for naught.

On the following Thursday, on resuming operations, no ozone or nitrous acid was detected in the laboratory, the preliminary tests on being repeated gave results as already stated.

TESTING FOR OZONE IN THE BLOOD.

A rabbit that had been well fed for a week was the subject of investigation. It was a big animal in fine spirits and weighed 4 lb. 3 oz. It was brought into the laboratory and both carotids cut through, and the blood collected in a sterilized glass receiver. In all 60 grammes were extracted and defibrinated with sterilized glass rods. The operation required nine minutes and the fresh serum was subjected to test.

The serum was diluted with distilled water in the proportion of 1 part of serum to 4 of water. With the iodide of starch an immediate reaction was observed in the open air, and the same reaction, faint at first, but gradually deepening in blue color, showed under a bell glass.

Testing with guaiac tincture of the officinal strength, which we reduced by adding an equal volume of absolute alcohol, responded more quickly to reaction of ozone. The blue ring around each drop of blood was marked and sharply defined. The same reaction continued when the test was made under the bell glass, and gradually approached a maximum of intensity at the end of half an hour, when to all appearances the ozone became completely exhausted.

The fibrinous clot with the entrapped corpuscles was likewise tested and gave a far more distinct and marked reaction than the serum.

It was evident at a glance that the corpuscles contained a far larger amount of ozone than the plasma.

The remainder of the defibrinated blood, about 40 grammes, which had been kept in a well covered jar, was next subjected to electrification for five minutes.

A galvanic current of 10 volts and 15 mil-amperes was sent through the fluid. The electrodes used being strips of platinum an inch long and ⅛ inch wide.

In six seconds the meter dropped to 8 mil-amperes, and the registration which was recorded at the end of each minute read as follows:

1	minute	7	mil-amperes.
2	"	5	"
3	"	4·5	"
4	"	3·75	"
5	"	3 +	"

Testing with iodide of starch and guaiac tincture showed the unmistakable increase of ozone. The rings around the drops of blood were of deep blue hue and the reaction continued on with much greater rapidity than was the case of the unelectrified blood. As quantitative test was out of the question, Dr. Dittrich made an approximation of the intensity of the action by comparing the rapidly deepening ring of blue with the chromatic scale given by Dr. Foer in his exhaustive work on ozone. They carefully noted the change of color as it progressed, availing themselves of the most advantageous light facilities, and agreed upon the estimate that the amount of ozone adequate to such reaction must be in the neighborhood of, at the lowest calculation, at least 2¼ times greater than the amount indicated by the reaction in the case of the unelectrified blood. The clot deposited around the electrode at the positive pole gave a more annealed reaction, the ring of blue almost approaching indigo, showing a most marked increase over the former reaction.

Standing by itself this test of the blood outside of the body signifies but little, for it is the blood that circulates through the living organism unimpeded with which we have to deal and in which physiological conditions alone can be of any value in the study of the action of the galvanic current. Yet withal when taken in connection with the tests that were afterward made, the observations form an important link in the chain of evidence that it is animal electricity which is the polariser of the atoms of neutral oxygen both in the plasma and in the hemoglobin.

Under normal conditions the transformation of O_2 into O_3 is slow and gradual and the polarization of the neutral oxygen is proportionate to the polarizing force of the existing animal electricity.

Undoubtedly Schmitt, Houzeau, Meisner, Kühne and others were right in their assumptions, but it seems to me that they did not probe deep enough for a solution of the possible origin of this transformation of neutral oxygen into ozone within the human economy. It was due to the polarization of the atoms of the neutral oxygen, but how did it come about.

I have assumed, in starting out upon the experiments the results of which form the title of the paper I have the honor of presenting to your consideration, together with the more exact details which I hope to announce at some future day, step by step, with the view of adding some light to the question, that this generation of ozone admits of a satisfactory scientific explanation.

During the years that I have devoted to the study of ozone within the body I have always regarded it with awe and veneration. I have woven theory after theory only to find that the strands broke precisely within the limits of the reasoning of the great observers to whom we owe all I know of ozone, and that to us as physiologists is indeed little.

That ozone can be found in the blood nourished by gases that contain no ozone is a fact beyond dispute, yet the problem of its generation is a problem that at first sight offers no easy solution.

In looking over the field of possible sources to explain this source of formation of ozone, it fastened itself upon me that one great factor that might afford an explanation of its generation had been overlooked. It was animal electricity, and I have tried to explain its function. There seems to be but one deduction to draw from the most careful observation, and that is, that it is animal electricity upon which not only the polarization of the atoms of oxygen, but all molecular polarization and chemical action in the body depends.

I believe that the transformation of oxygen into ozone within the body is brought about by this very animal electricity, which polarizes the neutral oxygen to such a degree that a portion of them rearrange themselves, attract and repel each other under this polarizing force until we get the ozone which we detect upon analysis. The function of the ozone is apparent to all of us. It gives the oxygen increased power to form combinations with the tissue elements and promotes oxidation.

This polarization of the oxygen seems to take place just as the gas touches the tissues where the conditions are favorable to such an action and where it closes circuit with electricity in the human frame. The unaffected molecules of oxygen under the vigorous spurring of this ozone become vitalized, as it were, and at once begin the search for their affinities in the tissues and enter into combination with them.

The proof of this reasoning seems to me to be apparent from the fact that I have been able to appreciably increase the amount of ozone in the blood by passing very weak currents of galvanic electricity through the body, and it is the underlying theory upon which I based my experiments and which I hope to make clear to you.

Before dismissing this portion of my paper and passing over to an account of our experiments upon the blood of the living animal electrified by a current of galvanic electricity, permit me to advance another theory which I regard as justifiable from my findings, and I do so only in the hope that it will give rise to careful discussion, for it is at variance with some of our pet physiological theories. It is that oxygen in the blood, stimulated by the polarizing power of animal electricity, and more so under the stimulus of the galvanic current, enters into combination with the hemoglobin of the corpuscles with a partial transformation into ozone, and that in losing its combining bonds it undergoes a further partial transformation into ozone.

EXPERIMENTS ON THE ELECTRIFIED ANIMAL.

This brings me to a record of the experiments upon the living animal with the galvanic current.

The animal chosen was also a rabbit, which was prepared by being fed on fresh vegetables for several days. He was in prime condition and was allowed to run at large until he was required for use. The batteries were carefully tested cell by cell and the current measured with both volt and mil-ampere meter. A coil of a resistance of 400 ohms, which had been placed in the circuit, was removed after the measurements had been taken, and we decided upon a current of a strength not to exceed 40 mil amperes.

Two cuts about half an inch apart were made into the skin of the animal, and into these and for a distance into the body of the muscle the platinum electrodes used in the previous experiment were inserted, and a current of 20 volts turned on. The meter showed 44 mil-amperes. This dropped quickly down to 41 mil-amperes. The reading of the meter during the five minutes that the current flowed was as follows:

1	minute	40·5	mil-amperes.
2	"	38	" "
3	"	37+	" "
4	"	35·8	" "
5	"	35	" "

At the end of five minutes both carotids were cut through and 35 grammes of blood were drawn into a sterilized glass vessel and defibrinated as before with sterilized glass rods.

It was observed that the blood was of a brighter scarlet hue than that which flowed from the arteries of the unelectrified animal. Exposure to the air while the process of defibrination was going on did not affect the bright tint. Defibrination, too, was not so easily effected, and the fibrine slowly gathered around the rods.

Seven minutes after the blood was shed a gramme of the fresh serum was diluted with two grammes of distilled water and subjected to tests with both guaiac and starch iodide. The reaction in both instances was almost immediate, a trifle more active with the guaiac. The ring of blue around the drops of blood was more pronounced and much deeper, and kept on deepening both in the open air and under the bell jar as had been done with the blood from the first animal killed. At the end of 20 minutes the test papers, those saturated with guaiac and starch iodide, three of each variety being exposed to the air and a similar number under bell jars, indicated the termination of the action, and they were taken out and carefully compared with the test records of the first experiment, which had been preserved in airtight tubes. The blue ring was even upon the most superficial examination found to be several shades deeper, and the ring of reaction was more spreading, in some of the drops almost half an inch wide and distinctly visible to the line of demarcation of chemical action. The fibrin also gave like results. A far larger amount of iodine had been set free in these tests than in the case of the first analysis. The quantity of ozone to give such reaction, according to a most conservative calculation of Dr. Dittrich, was estimated to be certainly three times greater than that which gave the reaction from the normal blood. The increase in the amount of ozone was astonishing and far beyond our expectations. We had anticipated some difficulty in determining the increase if it proved to be trifling, but here we were met by a quantity far in excess of what we had hoped to find, in the event of the most successful termination of our searching.

The action of the current on the oxygen in both the plasma and corpuscle enmeshed fibrin was evident in the transformation of a portion of it into the more vital form of O_3. That the current had accomplished this transformation, astonishing as it proved to be, was readily to be explained, but not so with the ozone in the normal blood. There was but one explanation for this—the polarizing action of the animal electricity.

MY PLAIN VIEWS REGARDING ANIMAL ELECTRICITY.

The existence of animal electricity is acknowledged. Its origin and action, however, are the points upon which electro-physiologists are not quite clear. Those who have given the subject some consideration dismiss it by establishing its connection between chemical action, heat and animal electricity. They rest contented in discussing the three conditions without attaching the slightest importance to the precedence of one or the other of them. Chemical action, we are told, evolves heat, and so tissue metamorphosis and oxidation go on. They are satisfied with the evidences of the existence of animal electricity, that it can be measured, and that it is one of the great trinity upon which life rests.

It is in view of this condition of the investigations

* Read before the Twelfth International Medical Congress, Moscow, Russia, August 19, 1897. By special invitation.

† Ber. d. Chem. Gesell., 12, 431; 15, 2291.

‡ Bulletin de la Société Chimique de Paris, September and November, 1889.

upon this question that I approach it with much trepidation and fear, lest I be charged with being too radical in my deductions. I can almost see doubt written upon the faces of many of this distinguished gathering and I can almost hear you say: Well, are you going to settle this question? Settle the question or not, still I have the boldness to advance a probable solution of the problem, and I ask you to follow closely my experimentation and the deduction I have drawn and based my opinions upon. I will not take up your time by rehearsing the observations of the various electro-physiologists who have enlightened us in animal electricity. To do so I would in fairness to all be obliged to begin with Matteucchi and so on up to the present day without omitting a single one, for each of the observers has welded a link in the chain of results, and to leave out a link would mean to destroy the integrity of the chain.

Let us for a moment consider the observations of Dutrochet and we may get a clew to the true function of animal electricity. He observed that if the positive pole of a battery be dipped into pure water and the negative in gum water, endosmosis continued more energetically.

Onimus later on discovered that with a reversal of this order of poles, endosmosis too was reversed. It is but fair, reasoning again by analogy, to assume that the electricity in the body exercises precisely the same physico-chemical action. I have already called your attention to the observations of Gay-Lussac. Whenever the so-called catalytic action takes place in the living tissue, is it not equally fair to assume that animal electricity is the prime mover? Can there be any question that electricity, a form of galvanic, with its electrolytic powers, of the ready manner with which it decomposes the salts, coagulates albumen in the vessels of our laboratories, has a like action on the tissues and fluids of the living organism?

It is apparent I hold that animal electricity not only influences the whole system of nutritive operations but also directs them.

Time and again I have electrified human beings and animals and observed that under certain conditions of electrification the animals and beings threw off a greater amount of urea and carbonic acid than under ordinary conditions.

Urea and carbonic acid! And what is the significance of such an increase in the waste products?

Nothing more and nothing short of increased chemical action, increased tissue metamorphosis, the increased evolution of heat; but the electricity, the animal electricity, that remains unaccounted for. Dutrochet and Onimus showed us the action of the anode and the cathode in endosmosis, and left us to apply it to the physiology of nutrition. Now let us do so, and account for the function of animal electricity if we can. As I have already intimated, the order of act on is animal electricity first, and why? Because we must have polarity before we can have chemical action and its natural result, heat.

Subject a solution of the iodide of potassium to electrification and you free the iodine. Inject a quantity of this fluid into the blood of a living animal and then subject the animal to electrification, and, in a very few minutes, starch papers held near in contact with the parts surrounding the positive pole will indicate that the iodine is set free by the action of that pole. Note the transfer of the chemical action from the laboratory to the living body—are the two not singularly alike?

Unfortunately, I have not been able to isolate the poles of animal electricity, and hence it is that my tests on animals similarly injected, yet not electrified, give me such indistinct reactions that we hesitate to announce them as positive results.

Yet all this points to the one conclusion and the one deduction—that animal electricity comes first; that is, the prime factor in all the processes of change, of chemical action or otherwise, within the living body. That without its stimulus of polarization, no chemical action can be called into life, and, consequently, none can go on, and tissue metamorphosis, which is life itself, must cease.

Before concluding, allow me a word or two upon ozone, its physiological and therapeutical value, which are not under discussion, and are hardly properly to be considered in the limits of this paper. We have dealt with ozone generated from the oxygen within the body, and it is in this form that it plays its so important role in the oxidation of the tissues. There seems to be some doubt as to the possibility of introducing ozone in its pristine integrity into the system. It may be a feat within the range of possibility, judging from the voluminous literature upon the subject that has been published only within the last year or more; yet, from my experience in handling it, I prefer to regard it as an agent that performs its most useful work upon the field where it is ushered into existence, where nature calls it into life because it is needed to perform important duties.

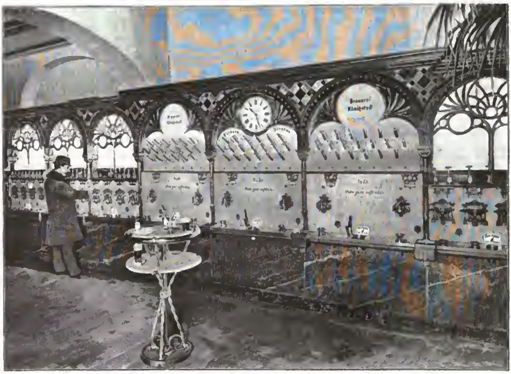
THE AUTOMATIC LUNCH COUNTER IN LEIPZIGERSTRASSE, BERLIN.

WE had occasion to refer in the SCIENTIFIC AMERICAN for December 5, 1896, to a description of a restaurant in the Potsdamerstrasse, Berlin, Germany, where visitors are supplied with food by an automatic system.

The counters are built into the walls, and are surmounted by panels in which the automatic delivery arrangements are located. These are mainly of two kinds: Such as provide solid food and others from which drinks can be served. A person wishing to take lunch in the establishment follows the series of panels, each of which is labeled, and drops his coin into the proper slot by which a plate is lowered to the counter and another brought into position for the next customer. If the lunch is to be supplemented with a glass of any beverage, a glass is taken down from a peg, rinsed in a jet of water, and again a coin is dropped into the proper slot. Now the corresponding tap is placed automatically at the disposal of the purchaser, but, being regulated by clockwork, it measures out to him just one glassful. There are tables at which one can stand for the meal, or, if he prefers to sit down, he can have a chair and put his plate on the shelf of the table.

The prices are plainly marked for each variety of food, and range from ten pfennig to fifty pfennig, or about from two to twelve cents, which represents considerably more in Germany than in this country. The full plates are in view of the customers. All is kept very neat and cleanly, and the paneling is very tasteful and



AUTOMATIC SERVING OF LIQUID REFRESHMENTS.

AUTOMATIC SERVING OF SOLID FOOD.

THE AUTOMATIC LUNCH COUNTER IN BERLIN.

even artistic, and the whole locality is calculated to stimulate the appetite. On the wall we see in one of our illustrations the word "Bediene," which is the first word of the inscription "Bediene Dich Selbst" (help yourself), in imitation of the well known "γνῶθι σεαυτόν."

No doubt this arrangement will be found quite satisfactory, as the automatic distribution of tickets at the railway stations of the German capital has been, for, on one hand, the purchasers are free and undisturbed in their selection, and, on the other hand, the management of such a restaurant is very simple, requiring very little personal work. Such work is restricted to the preparation of the meals, and the refilling of empty plates and tanks. For our engraving and the foregoing particulars we are indebted to Ueber Land und Meer.

OUR GREAT GRAIN CROP—FUTURE OF THE BUSINESS.*

THE MOVEMENT OF THE CEREAL FOODS IN THE WESTERN HEMISPHERE: THEIR PRODUCTION, TRANSPORTATION, DUTIES AND CONSUMPTION.

By Dr. William P. Wilson, Director of the Philadelphia Commercial Museums.

In an assembly of millers at this time the unusual conditions of the grain and flour market in the immediate present are likely to be of more interest and attract more attention than the possibilities of future markets under normal conditions. As wise business men, it is well to forecast the future possibilities and, if in our power, to provide for a permanent outlet for our surplus flour, even when other wheat-producing nations have good harvests and are likely to export their usual quantities of wheat and flour.

The best authorities claim that the probable requirements of European importing countries for 1897 and 1898 will be 411,200,000 bushels, of which Great Britain will require 180,000,000. The actual exports during the year ending July 31, 1897, were 366,440,000 bushels, of which the United States and Canada exported 138,000,000; Russia, 112,000,000; Turkey and the Balkan States, 70,000,000; Argentine, 3,400,000; India, 1,040,000; Austria-Hungary, 22,000,000. After making all allowances, the United States and Canada will have to export 300,000,000 bushels of wheat to meet the demand of Europe, or 202,000,000 bushels annual amount larger than has been ever exported to Europe from these countries—in addition to what is needed for extra-European countries.

We congratulate the farmers and millers of the country on the prospects of the present year; but, realizing that other conditions may exist in another year, when Europe will not require so much from us, we feel it is the part of wisdom to look for other markets. In Europe we are liable to meet—as we have met—competition from other European countries and from Argentine, Australia, India and Egypt, which will cause the prices of flour and grain to fall below that which would return a fair reward for the labor employed in producing them. During the last twenty-five years the average annual exportation of wheat and flour has been 258,000,000 bushels from all exporting countries and 111,000,000 annual from the United States. During the last five years the average annual exportation from all countries has been 345,000,000 bushels, while that of the United States has been 164,000,000; so that, despite the fact that new wheat-producing countries like Argentine, Australia and Roumania have entered in the race, the United States still holds about the same percentage of the total amount exported. In Europe, the number of competitors is increasing to such an extent that if it were not for other markets, we should be in a sad plight before many years. In flour the United States has fallen off 2,000,000 barrels in amount exported, from the year ending June 30, 1893, when 16,620,339 barrels were exported, to the year ending June 30, 1897, when only 14,569,545 barrels were exported. During the year ending June 30, 1896, 14,000,211 barrels were exported—Great Britain taking 8,211,236 barrels; Brazil, 871,475; Hong-Kong, 890,000 barrels; Canada, 802,000 barrels. Europe, with all her millions of people outside of Great Britain, took less than 1,000,000 barrels, while the countries south of us took 3,000,000 barrels—almost as much as all the rest of the world combined outside of Great Britain. Asia, which has not been considered, until of late, as a market for flour, takes over a million barrels.

The market to which Americans will have to take their surplus flour is the country south of us (the Atlantic countries), South Africa, and the Asiatic countries. European countries are more likely to import our wheat and make their own flour; while the other countries are more than likely to continue to do as they are now doing—import more flour than wheat. Of the 21,000,000 cwt of flour imported by Great Britain, 15,100,000 cwt. came from the United States; 1,932,100 cwt. from British North America; 1,602,000 from France; 1,398,000 from Austria, and 204,790 cwt. from Germany. In Europe we not only have to meet the competition of the other wheat-producing countries, but nations like France will import wheat and turn it into flour and compete with our millers in the British market. In the new market of South Africa we have made rapid strides. In 1895 the whole of South Africa imported only $111,750 worth of flour. In 1896 they imported $945,000, almost a million dollars. From the United States in the month of March, 1897, the importation was 300 per cent. greater than the corresponding period of 1896; that is, for the month of March, 1897, 300 per cent. greater than in the same month of 1896, showing the rapid growth of the export of flour to that country. The statistics of Cape Colony show that in 1896, of 13,896,392 lb. of wheat flour imported, over thirteen million came from the United States—seven million from the Pacific and six millions from the Atlantic coast of the United States. The tariff on this flour was $1.22 per cwt. The remarkable increase of exports to Asiatic ports in the last decade from 409,147 barrels in 1887 to 943,673 barrels in 1896 shows a gain of over 100 per cent.; and for nine months ending March 31, 1897, 882,204 barrels, which reached a million barrels before June 30, 1897. The shipments in this direction were mainly flour, and therefore of more interest to a miller. In Japan it appears that the capacity of that country for wheat production has not increased as rapidly as the population; and, therefore, the need of importation. Japan with her 42,000,000 and China with her 400,000,000 inhabitants—once the habit of using flour becomes general—will become a market capable of taking any surplus that we have. In China and Japan wheat is admitted free; while in most European countries flour is discriminated against by levying a higher duty on flour than wheat. This trade will not be held by the Pacific millers alone. Of the 30,000,000 cwt. flour imported by Great Britain from the United States, 20,000,000 comes from the Atlantic and 10,000,000 from the Pacific coast, that is, that goes to Great Britain. The extraordinary increase in the last few years of exportation of flour to Asia gives a reason to look for the continuation of the same increase in the future; and in this market European nations are not likely to compete.

In South America, Argentine, Chile and Uruguay are exporters of wheat, and Argentine and Chile exporters of flour. Chile exported, in 1895, 40,621 barrels, of which 16,300 went to Peru, 19,720 to Ecuador, 400 barrels only to Colombia and 77 barrels to Guatemala, leaving about 4,000 to be distributed among Bolivia and other nations. The Argentine Republic exported in 1895 606,000 barrels of flour, of which 535,000 went to Brazil, the remaining 70,000 being scattered among England, Germany and other nations. Of the 301,000 barrels exported in the first six months of 1897 from the Argentine Republic, 299,000 went to Brazil—almost all of it. Very little Argentine flour goes to Europe, owing to the danger to the condition of the flour in crossing the tropics, which is not a matter to be disregarded.

The countries south of us, that are possible markets, have a population of 33,000,000 inhabitants, including Mexico, Central and the South American countries; and some of them are now importers of flour. At present Brazil takes 871,478 barrels; British West Indies, 572,842 barrels; Central America, 250,000 barrels; Venezuela, 218,000; Hayti, 197,000; Cuba, 176,000; British Guiana, 167,000; Colombia, 138,406; Porto Rico, 120,021; French West Indies, 109,118; and in other countries in smaller amounts, giving a total of 3,000,000 barrels, a market second only to that of Great Britain, and one in which Argentine alone is a large competitor, the amount of Chile's export being small, and her location excluding her from a large part of this territory. With these countries we should endeavor not only to hold, but also to increase our trade. Reciprocity in the past has done something to increase this trade, the effect of it in Brazil and Cuba being quite marked, as well as in Germany and France.

During the time when we had reciprocity with Brazil we had the following conditions: Brazil placed wheat, corn, seeds, flour, oil, coal, machinery and tools on the free list, and reduced the tariff on a number of other articles 25 per cent. in order to avoid a tax on coffee and secure admission free for her sugar. The effect on flour can be seen from the following: Two years before reciprocity came into effect, in 1890 (first year), we sent 687,342 barrels to Brazil; in 1891 we sent 722,369. Those are the two years preceding reciprocity. The first year of reciprocity we increased from 700,000 to over 900,000 barrels; and the next year (1893) we dropped off a trifle to 887,000; in 1894 we went up to 920,896 barrels. After that reciprocity was dropped. We dropped immediately the next year to something like 700,000 barrels. Flour during reciprocity was admitted free, now it is taxed at 57½c. a barrel. That is extremely low. In Cuba the effect on flour was as follows: Before reciprocity 114,000 barrels (the last year before introduced into Cuba); the next year it went up to a trifle over 300,000 barrels; the next year (1893) to over 600,000; the next year (1894) to 662,000; and the very first year that reciprocity was dropped it went down to 255,000. For Cuba, prior to reciprocity the tariff was $3.35 per barrel on flour. It was reduced to 88c. during reciprocity, and increased to $3.66 after. In Cuba free sugar was gained by the reduction on American products; in Brazil, free coffee and other things. Our great drawback is the high tariff imposed upon flour in most of these countries, largely for revenue purposes, but also, in some countries, to protect the home market. Reciprocity, therefore, might improve some of this; and, if it can be done, perhaps the 200,000,000 barrels of flour which we have dropped recently in our exportation since 1893 would be brought back again by reciprocity. If it could be so, it would be an object well worthy of the most arduous efforts of this association. If without reciprocity we are able to sell Brazil more than Argentine, her next neighbor, sells, how much more we would be likely to sell with reciprocity no one can say.

As Argentine is our greatest competitor, would it not be well to look more closely into her capabilities? The area of Argentine which is suitable for cultivation of wheat is 240,000,000 acres. Argentine takes in the whole of the southern part of South America; now includes Patagonia and runs up well north into the middle part of Brazil, the upper part being tropical; the whole middle part being temperate, and when you get down as low as Buenos Ayres, you have a climate not as cold as here—having frost and a little snow in winter, sometimes, but a very mild climate; and the whole of the region for many hundreds of miles north of Buenos Ayres and a great distance south is a wheat growing region, with very rich lands. Of the 240,000,000 acres in Argentine suitable for wheat growing, there are at the present time only a little over 7,000,000 acres cultivated for wheat.

In 1894, Argentine's best year (grasshoppers have eaten the wheat up, mostly, during the last year), Argentine exported 59,000,000 bushels of wheat and 459,527 barrels of flour. In 1895 it dropped off to 35,000,000 with, however, a little more flour (607,000 barrels of flour—the mills were increasing); in 1896 the exports dropped to 21,000,000 bushels of wheat (remember, in 1894 it had been 59,000,000), and the exportation of flour dropped down to 472,000 barrels; in 1897—a very bad year for the Argentine—the exportation of wheat was only 3,000,000 bushels and the flour 301,000 barrels. Twenty years ago, however, Argentine imported wheat and flour for her own consumption. Now it is the third wheat exporting nation; and although, at present, it is not a very important factor in the market, it will no doubt, in future, be a very large exporter of wheat and flour. In the Argentine Republic the cost of the production of wheat is estimated at 21 cents a bushel, not including cost of the land.

The average freight to Europe is only 15 cents a bushel; the nearness of the railroad stations to the seaboard averages only a hundred miles, as against the 1,000 miles of American travel. This is an important factor in favor of Argentine. There are in the Argentine Republic at the present time 416 flouring mills, of which 276 have modern machinery and are capable of producing 14,806,000 barrels of flour; but the actual output for consumption and export does not amount to more than 30 per cent. of this. In addition to the 276 mills are 18 second class and 122 third class mills. A factor in the price of wheat, and also of flour, is the low cost of living; the small farmers (who are principally Italians) live on a scale that the Americans could not endure; and with large families, all of them—from grandmother to children of tender years—joining in the work, they are able to put wheat on the market at a less rate than the American. If it were not for the poor facilities of handling the wheat from the farm to the railroad, they could produce it cheaper. They have no barns and are compelled to hurry the grain to the station as soon as it is harvested. Here there are rarely any warehouses; and the crop suffers much injury before it reaches the seaboard. At the wheat moving season in the Argentine Republic it is not uncommon to see, stacked up, hundreds of thousands of sacks of wheat at the stations without any covering. The different kinds of wheat grown in the Argentine may be of interest. Barletta, a hard red wheat, is principally grown in Santa Fe; the wheat from Antre Rios is somewhat superior; the wheat grown by the Russian farmers near Pramenti has a high reputation. Barletta varies in color, size and plumpness, sometimes looking like the original barletta seed that came from Italy, but always containing a considerable amount of gluten. The Tussala wheat is smaller, gray-back, with less strength but better color; and is sometimes not easy to distinguish it from the interior Russian, Bulgarian or Lombardy wheats. French wheat is grown considerably in Buenos Ayres because it gives a very large yield; but it is more tender than barletta. It is short on gluten. The Bahia blanca wheat is the nearest like the American red wheat.

The Uruguayan wheat is not as good as the Argentine wheat, being deficient in strength. There is a great irregularity in the River Platte wheat, which is also augmented by the bad handling afterward.

In order to develop trade with southern countries on this continent, it will be well for millers to familiarize themselves with facts concerning the existing trade of these countries. The statistics of the United States show that no flour was exported to Argentine, Uruguay, or Paraguay, and to Chile and Bolivia practically none—the amount was so small; all of these but Bolivia and Paraguay being wheat exporting countries and supplying their own wants, and these two being largely supplied from their neighboring countries. Peru takes only 6,000 barrels and Ecuador 20,000—their wants being practically supplied by Chile. These two countries might be reached from the Pacific coast, but not from the Atlantic. The 3,000,000 barrels were mainly sold to Brazil, West Indies, South American countries on the Caribbean Sea and Central America.

Brazil, with her 14,000,000 population and the next largest customer for flour after Great Britain, has four flour mills only, for which wheat is largely imported from the River Platte—17,000,000 bushels having been imported in 1894. These mills are graded: First, the English flour mill—the Rio de Janeiro—50 sack plant (meaning 280 bushels to a sack); one fluminense of Rio de Janeiro—30 sack plant; another of the four mills only a 5 sack plant, and another only three; that comprises the local mills of Brazil. The market in Brazil can be, contrary to general opinion, reached by a number of lines. There are regular steam lines from New York—among them, that of Slohmann & Prinz; and in addition to these there are a number of packet lines whose rates would be considerably lower for Rio and other ports. For more northern ports there is the Red Cross Line and one or two others; and sailing vessels could also be used. In the northern ports there are practically no competitors; and the only problem is to get sufficiently low rates to enable the flour to be sold at a price to find purchasers. In Rio, Argentine enters into competition; but as American flour is preferred, and sells, too, at a higher rate, there is no doubt, if trade were pushed and rates could be made low, it would enable the American flour to drive the ordinary flour out of the market; and especially if, under reciprocity, American flour was admitted free, instead of paying 57½c. duty, the Brazilian trade would take a million barrels instead of 75,000, as in 1896—if the millers would take the matter in hand and do the business promptly. The brands most quoted in these markets are Richmond 1 and 2 and Baltimore 1 and 2, and always at a higher price than the Argentine and Brazilian. Brazilian importers of flour claim that the market could be greatly enlarged if rates could be made lower, which could be done if sailing vessel rates could be obtained.

Cuba imported 664,000 barrels in 1893 under reciprocity and fell off 379,000 after reciprocity, taking in 1897 only 176,000 barrels, owing to conditions caused by the war. Cuba, under normal conditions and under reciprocity, could be counted on for 500,000 more barrels than last year. That would make 600,000 or 700,000, or one-fourth of the whole deficiency which we are now laboring under.

Mexico exported 645 bushels of wheat and 3 barrels of flour and imported 50,000 bushels of wheat and 46,819 barrels of flour. Although it has 12,000,000 population, it imports very little flour. First, because it is, contrary to general belief, a wheat-producing country and it is able to supply its own wants to a large extent; and, secondly, because of the high tariff, $4.30 a barrel, with 7 per cent. stamp duty added.

Now, a word about Venezuela. Venezuela imports 218,224 barrels, which amount would be much larger if it were not for the high duty, the duty on flour, including the internal revenue, amounting to 2½ cents per pound. Practically all the flour used in this country is imported from the United States, a very small amount also from Austria. The consumption is not great, as it is only used by the wealthy people. The grade used by the ordinary people throughout Venezuela is made from corn prepared at mills located in the various cities. The corn raised in the country is entirely raised for home consumption, and to protect this the present duty is established. Venezuela has declined to reduce the

* An address before the Pennsylvania State Millers' Association.

duty on flour, claiming that if the flour is imported it will come into general use and destroy the market that now exists for their own production of corn.

Guiana, Central America and the West Indies are so situated with reference to the United States as to make it possible for our millers to undersell all their competitors. If it were not for the high tariffs in all these countries, a much larger amount would be consumed. In the countries south of us, whose products are largely consumed by the United States, reciprocal arrangements would be desirable and beneficial to both parties. The possible increase of trade in these countries would probably give over 1,000,000 barrels out of the 2,000,000 we have fallen off, and the new markets in Asia and Africa would make another million. Familiarity with the tariffs, freight, customs and languages of these countries would greatly facilitate this trade.

To aid in bringing about this result, the Philadelphia museums have been established. In order to build up trade with foreign countries, it is necessary to go to work in a practical way. Certain points must always be considered—use, demand; the demand and the supply; by whom and with what particular duties; the prices at which (with the duties added) goods are bought and sold; the freight and duty to which they are subject; and, lastly, the houses that handle them. The general reputation of theses houses must be examined and every item connected with the shipment of goods and collections of payments must receive consideration. All this and much more is done by the Philadelphia Commercial Museums.

[Continued from SUPPLEMENT, No. 1131, page 18094.]

THE SCIENCE OF HUMANITY.*

By W. J. McGEE.

5. THE most elusive attributes of humanity are those manifested in conduct and feeling and thought; yet, paradoxically, it was these obscure products of intellectual activity that men first sought to guide and control, for in every generation in each stage of culture, from the lowest savagery to the highest enlightenment, parents have essayed to train their children, while first the tribal leaders and later the sages and statesmen have, semi-consciously or in full consciousness, striven ceaselessly to shape the mind of the masses. So education, or the voluntary control of individual mentality for the common good, has affected profoundly the entire course of human development and has served ever to widen the chasm separating man from the beasts. In the earlier stages of culture, as indicated by the customs of savages still living, education was limited to the lowly esthetic and industrial activity of the prime; for the primitive thinker ascribes motive, complex feeling, and all but the simplest actions to ill conceived extraneous potencies against which it were bootless to strive. In higher savagery and in barbarism, the sphere of education extended to those features of conduct involved in the maintenance of tribal relations, and was effected partly by means of habitual appeal to the extraneous potencies, which were gradually crystallized in mythic systems themselves arising in a certain order determined partly by educational practice; for in much of savagery and in all of barbarism the sources of sentiment and motive are sought outside the individual and largely beyond the realm of the real. With the birth of civilization, education extended to feeling and thought, partly through appeal to ideal potencies, and there was a tendency to exalt the esthetic and neglect the industrial; and certain educational systems rose so high into the supernal or passed so far into the metaphysical as to lose sight alike of individual conduct and of the sources of real knowledge. In modern enlightenment, especially in America, the methods and purposes of training are shaped by science, and, despite the struggle of the scholastics, education is becoming revolutionized. With the recognition of an actual universe knowable through sense and reason, training becomes definite in plan and useful in purpose; with the recognition of cerebral function and of the influence of exercise in developing the brain, the scientific psychologists of the present decade have gone far in erecting a new platform for pedagogy; and with the recognition of the relations among the activities and the activital products of man, the normal course of intellectual development would appear to have been made clear, for it seems manifest that just as observation begins with the simple and proceeds toward the complex, and just as activity begins with the spontaneous and passes into the volitional, so individual and collective mentality must arise in simple and perhaps spontaneous action, to grow through habit into sentiment, and to mature through unconscious or conscious thought in definite motive. It is heterodox, perhaps in more senses than one, to affirm that motive—the noblest character of humanity—finds in spontaneous action, blossoms in subconscious habit, and attains fruition in the highest intellectual activity, whether unconscious or conscious, of which the individual or group is capable; certainly the affirmation represents complete inversion of a notion dominant in savagery, prevalent in barbarism, and gradually weakening through civilization; yet it is sustained by all that is known of the processes of acquiring knowledge, by the history of the growth of knowledge in general, and, indeed, by nearly all applied statecraft and most applied priestcraft throughout human history. The recognition of the genesis and antecedents of motive must afford a vantage point for a clearer survey of the vast field of human emotion, affection, passion, aspiration, disposition; and, at the same time, it cannot fail to give a keynote for improved education, for the still more complete control of mind.

These are but a few of the many ways† in which the great science based on human activities tends to bring order out of that vast chaos of action and thought which has so long resisted analysis and synthesis—that last citadel of the unknown.

AND OF THE BASIS AND END OF THE SCIENCE OF HUMANITY.

Hitherto humanity has been the theme of poesy and romance rather than of sober science. All men have perceived that their kind possess attributes distinguishing them from the rocks and plants and beasts of lower nature, yet for the most part these attributes were either ignored or transfigured into a dazzling halo which defied analysis none the less by reason of its subjective character; even to-day and in the most enlightened circles of the most enlightened nations there are few willing to consider and content to consider dispassionately the purely human attributes; but to these few the chaos of industries and ideals, of emotions and passions, of conduct and motive, and of all other things human falls into a simple order nearly as definite as the order recognized in each of the older sciences—the order of human activities and activital products.

Exact knowledge began with the remote and progressed toward the near. With every stage of progress it has been a power for the conquest of natural forces and conditions, has exalted intellectual mankind above all brainless or small brained creatures, and has made continually for human welfare and happiness; and now that the methods and purposes of science are extending to the human body and brain it cannot be doubted that these, like all other material things, will be controlled and reconstructed for the good and the glory of intelligent man. This is the end of the science of humanity.

* Continuation of a paper read before the American Association for Advancement of Science, August, 1897.

† One of these is the control of society itself for the common good, as known by Ward in his masterly memoir on "Dynamic Sociology," which it must suffice to mention merely.

THE BRITISH ASSOCIATION—ADDRESS IN MECHANICS.

THE address in Section G was delivered by Mr. G. F. Deacon, M.I.C.E., who referred to the great progress which has been made in mechanical science. After some introductory remarks, he said: It is not proposed to discuss the progress and prosperity which mechanical science has brought about in the Victorian era, much less that which the succeeding years will yield; but I venture to think that a proper subject for consideration from this chair, if not for discussion in this section, is to be found in any unnecessary waste of energy which may occur in the process of mental development of the men who are to succeed us in the great work to which we devote our lives. Having myself passed as an ordinary apprentice through workshops of mechanical engineering in the old days when working hours were longer than they are now—from six in the morning till six in the evening—and that, too, on the banks of the Clyde, where no special indulgence was given to what was sometimes called the "gentleman apprentice," and feeling convinced, as I still do, of the immense and permanent advantage derived from that experience, I shall not be judged to underrate its value in the case of others who have yet to choose the details of the career by which they expect to gain a place in the profession or business of an engineer. On the other hand, as a student thirty-four years ago under the late Prof. Macquorn Rankine and the present Lord Kelvin, I shall not be prone to underestimate the advantages of academical training in its proper application to the profession to which I am proud to belong.

TRAINING OF ENGINEERS.

Do not suppose that I think the training of the born engineer should not be controlled. He will stand head and shoulders above the rest of us whatever we may do with him; but in order that his exceptional parts may not wreck him as an engineer, and in order that his energies may be rightly directed at the start, he, too, should have the advantages of that systematic training which to his less gifted brethren is becoming more and more absolutely essential to success. At the time I began practice the large majority of young engineers were left entirely to their own devices so far as the attainment of any scientific knowledge was concerned. As pupils or apprentices, articled or not, they entered an engineer's works or office; for a certain number of years they had the run of the place and some encouragement if they worked well, but it could not in the nature of things, amount to much more. This was a very necessary, perhaps the most necessary, element of their training; but except to the few who were so constituted that with little or no guidance they could supplement their practical knowledge with the study of principles elsewhere, it was entirely ineffectual in the production of that well balanced attitude of mind which any person who properly assumes the name of an engineer must hold toward every engineering problem, great or small, which he is called upon to solve. And so strongly have I felt this, that in the earlier days, when there were fewer schools of practical science, and when their utility was little understood, I required, wherever the matter was under my control, the insertion into the articles of apprenticeship of a clause by which, at some inconvenience to the office, the pupil was required to attend two sessions at the science classes of Glasgow University, or at some other approved school of practical science; and without this condition I declined to take the responsibility attaching to the introduction into the profession of men who, in their earlier careers, from no fault of their own, had not even acquired a knowledge of what there was to learn, much less of how to learn it. More recently this course has become generally unnecessary, for in Westminster at least the young engineer rarely enters an office until he has acquired some knowledge of what he has to learn. He enters, in short, at a much more advanced age than formerly. When it is essential that he should be earning something soon after he comes of age, anything like a complete training is an impossibility; his work ceases to be general, and his practice is more or less confined in a much narrower sphere than need be the case if the pursuit of further knowledge continues to be his chief duty. It is not desirable, at least so it appears to me, that even at this stage his training should be specialized in view of the particular branch of the profession or business he is likely to follow. The fundamental principles of any branch of mechanical engineering are broadly the fundamental principles of any branch of the profession.

In America I understand that a college course of engineering generally includes workshop practice designed to supersede the old system of apprenticeship to a mechanical engineer. This fact and other important differences between the English and American practice have only lately come to my knowledge, and before they did so the substance of this address had been written. It might, in some particulars, require modification as applied to Canada, but it remains the result of my observations concerning the conditions of engineering education which obtain in the mother country. A few words now in relation to that physical and mental training gained laboriously, and somewhat wastefully as I think, at the joiner's bench, in the fitting and turning shops, the foundry and the forge, during the old course of mechanical engineering apprenticeship. I am convinced that the kind of knowledge which comes of thoughtful chipping and filing and turning and forging, though only applied to a few of the materials with which, in after life, the engineer has to deal, are quite as important as tables of density and strength to his future sense of rightness in constructive design. The use of such work is not merely to teach one the parts and combinations of any particular machine; in a still higher degree it is the insensible mastery of a much more subtle knowledge or mental power, the application of the senses of sight and touch and force, it may be of other senses also, to the determination of the nature of things.

The compulsory inclusion of the principles of all such subjects as chemistry, electricity, geology, and many others, in science courses intended for a future engineer is desirable, not only because a fundamental knowledge of them leaves open a very much wider field from which the engineer may, as opportunity offers, increase his knowledge and practice in the future, but because many of such subjects are inseparable from an intelligent understanding of almost any great engineering work. "Nothing so difficult as a beginning" may be a proverb of rather too far reaching a nature, but it contains the suggestion of a great truth, increasing in weight as we grow older, and the beginnings of such collateral sciences should therefore find a place in every engineering student's store of early knowledge.

AUTOMATIC EXTINCTION OF LAMPS.

AN ingenious arrangement of street lighting, which allows a reduction of the illumination at any time when less light is needed, is described in the Electrical Review. This arrangement is now in use in several places, but Portsmouth, England, is considered a notable instance, as the system has been successful there. It appears to be a system of automatic switches. "The automatic switch, which is being used on 240 lamp posts, is designed so that, when the arc lamps are turned off, the incandescent lamps are automatically lighted." It ought to be explained that each lamp pillar has an arc lamp as well as two incandescent lamps, the latter being employed during the period when the lesser illumination is desired. "The device consists of a coil in series with the arc light, and, when the arc lights are burning, the coil becomes energized and attracts the end of a lever; when, however, the arc lamps are extinguished, the rocking arm drops down upon a knife edged switch, and this action has the effect of completing the incandescent circuit, thereby turning on the glow lamps." The paper quoted illustrates this arrangement by engravings which cannot here be reproduced.

The operation, however, is so simple that its general features may be understood without engravings. When the lever spoken of drops, the incandescent circuit is completed, the current passing through a tube straight to the lamps, returning to the switch through the arm of the lever and out again. This provides for the lighting of the glow lamps at the instant of extinguishing the arc light. The extinguishing of the incandescent lamps, in their turn, is accomplished by sending a reverse current through the arc lamps, and consequently through the coil, thus lifting the lever out of the switch and cutting out the incandescent lamps. To prevent the lever from falling back again into the switch, a permanent magnet is pivoted under the solenoid in such a manner that it may move horizontally. This magnet carries a catch, which, passing under the arm of the lever, holds it from falling back on to the switch when the current through the series coil is interrupted, while, at the same time, it permits the core of the solenoid to drop down to its original position. To insure that the lamps are all effectually cut out, the reverse current is turned on for about five minutes. When the current for the arc lights is sent through the lamps, the pivoted magnet which operates the catch is drawn back into its original position, which leaves the lever free to act, according as the coil is magnetized or demagnetized. The use of this apparatus in Portsmouth is estimated to have saved the wages of three men.

"In view of the continually increasing employment of iron in building construction," says the Revue Technique, "it is well not to lose sight of the disastrous action exerted by lime and plaster of Paris on this metal. If we plunge pieces of iron into a vessel of freshly prepared lime, a rapid oxidation takes place, especially if wrought iron or laminated iron is used. This oxidation is not confined to the surface, but rapidly reaches the heart of the iron, which in a very short time undergoes a profound alteration in resisting qualities. To this must be added the great expansion caused by increase of volume of the mass. It has been shown thus that iron frames put together solidly by means of clamps were nevertheless broken. The action of plaster of Paris is similar. On the other hand, cement seems to be an excellent preservative against rust, and it has been shown that pieces of iron covered with a thin layer of cement remained unaltered after being for a considerable time under water. It would even seem that such a covering is preferable to painting with red lead."

The perfect construction of a bicycle wheel so as to obtain an equal degree of tension upon each of the spokes is a matter of no little difficulty when it is computed that a single turn of the nut holding the end of a spoke in the rim may make a difference in the pull of some 50 lb. or 60 lb. and leave a very slight margin of safety, if any. From a highly interesting article on the subject contributed to our contemporary the Engineering News, we find that the results of tests proved a difference in the tension of high grade bicycle wheel spokes of as much as 100 per cent. between extremes. Presumably this great difference is the result of the employment of wood rims, which are almost universal in the United States, but it emphasizes very clearly the advantage derived from the use of the pneumatic tire in taking up shocks due to the unevenness of roads.

HEATING AND VENTILATION BY MOISTENED AIR IN SPINNING MILLS.

PORTER & LEWIS APPARATUS.—In this (Fig. 1) we find the funnels, set one into another, of the Roger Pye apparatus. Four apparatus of the same kind are usually arranged around the same center at which the steam pipe ends. This is clearly shown in Figs. 2 and

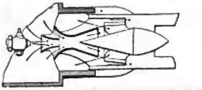


FIG. 1.—PORTER & LEWIS APPARATUS FOR MOISTENING AIR.

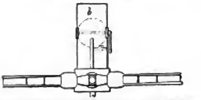

FIG. 2.—APPARATUS WITH FOUR ATOMIZERS.

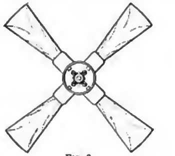

FIG. 3.

3, the former of which shows in addition the tube through which the cool air enters under the control of the register, b.

The Tattersall Apparatus.—The air under pressure is admitted through the large central conduit, a section of which is seen in Figs. 4 and 5, while the water circulates in the pipe situated immediately beneath the preceding. The two fluids make their exit through their respective ajutages, and the two jets, in crossing each other and in impinging against the screen placed opposite the air ajutage, become mixed. The air of the

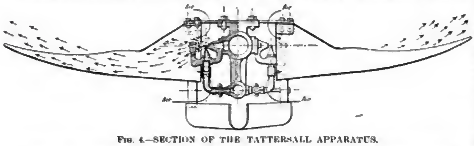

FIG. 4.—SECTION OF THE TATTERSALL APPARATUS.

room, sucked by the gaseous current, becomes also mixed with them. The whole makes its exit through inclined nozzles. The water in excess is collected by the pipe situated at the lower part of the apparatus.

The Josephy Apparatus.—The water enters the revolving funnel, h (Fig. 6), and participates in its motion. The centrifugal speed which is thus given it projects it through a circular felt filter, b, into the drum, f. Here it meets with the current of air sucked in at o by the exhauster, d, which carries it along and causes it to make its exit from the apparatus in the direction shown by the arrows. But all that is carried along is the fine drops of water. The too large drops, which are thrown into the drum, f, impinge against its wall, and, along the latter, descend into the tank that is formed by the base of the drum, and that is connected with piping which leads the water in excess to the exterior. If the mist carried along by the current of ascending air contains dust, this is projected against

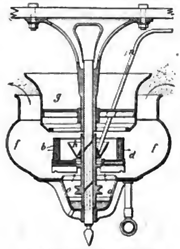

FIG. 6.—JOSEPHY APPARATUS.

the vessel, g, moves along its walls and falls into the tank, so that a fine vapor is alone sent into the surrounding air. The pulley that drives the apparatus is situated to the right of the orifices, o.—Revue Industrielle.

THE CONTROL OF FIRE.*

IT ought to be of special interest to correctly define the work of professional firemen. The term fire extinguishment, which is supposed to describe the work performed by our fire departments, conveys no adequate idea of the duties and responsibilities incident to the modern conditions of fire duty. For that reason I have, as on an occasion hitherto, preferred to designate all the duties of a fireman as those which have to do with the control of fire. The control of fire signifies all that we commonly ascribe to fire extinguishment and a great deal more. The uncertain attempts at fire extinguishment practiced by any one under the exigencies and the circumstances that surround the occurrence of fire, where there exists no regularly organized body of men maintained solely for the purpose of extinguishing them, separate the field of fire extinguishment, so called, from the strict application of the control of fire exercised by proficient firemen with the efficient apparatus, and by a body of men who are under constant discipline, and engaged exclusively and constantly for this duty and service. It is within a recent period of time that the control of fire has animated and guided the operations of our fire officials. Previous to the year 1865 the conditions and limitations under which firemen performed their duties forbade the present successful results, and the judgment of experienced firemen in many of our volunteer fire departments, aided by an earnest and willing corps of men, could not prevail against losses due to inefficient apparatus, a lack of discipline, and other features which combined against successful results. The elements that have contributed signally to the advance of the control of fire were a trinity of causes operating simultaneously, and from the beginning of which I date the modern period of fire extinguishment. I refer to the installation and usage of electricity in connection with the fire service, to transmit alarms of fire, and especially through the installation in its best form of the fire alarm box, permitting ready communication and announcements of fires to be communicated instantly, and giving a reasonably definite location of such fires.

Second, to the introduction of the steam fire engine, and then, as a third cause, the establishment and maintenance of a regularly organized fire department, supported entirely by the municipality, and engaged wholly and constantly in the fire service. It is perhaps within bounds to say that the establishment of a paid department, which really means the engagement and constant service of a body of men trained and skilled in the art of fire extinguishment, has done more to advance this service, and in every way has worked for the surer and readier control of fire, than all other causes. It is clear that this must forever remain so, for no apparatus, however powerful, or no other conditions can be successful, unless, after all, the work is intrusted to a body of men whose judgment, experience and skill will produce the results which these inanimate helps toward fire extinguishment are capable of rendering. It is true there are other reasons, which contribute to and supplement those mentioned, in enabling the firemen to attain a readier control of fire. Well paved streets, an efficient police department, abundant water supply, adequate width of streets, building regulations, defining materials allowable for use, and giving rules pertaining to construction, and many other matters, have an important influence upon fires. The precise thing which I mean by control of fire is its mastery with the smallest amount of loss, not money loss, since fire has no measurable sense for the purpose I mean, but the least loss of that material which may be in process of burning, and its control in the minimum of time; in other words, the least loss of what was liable to be consumed, and its extinguishment in the least measure of time. The successful control of fire carries with it the responsibility, intelligence, ability, judgment, skill and experience which will enable a fireman upon arriving at a fire to definitely and instantly conclude where his point of control will be. Of course, it is a question of contention whether fires at certain stages are controllable.

It is certain that in our larger cities the whole building art is changing to an extent that requires a readier control than has ever been exercised to prevent a calamitous fire. The height and character of the structures of prevailing type, of steel frame construction, with such immense window and light area, makes such buildings far more subject to fire externally than is commonly supposed. They are far more susceptible to fire from exposure than many inferior buildings, and the extent of a fire within them, if once communicated to them, depends largely upon the character of their contents. To understand the application of the rules for the control of fire, I would classify the risks of fire in this manner. First: The contents risk, being the fire liable to the contents of a structure. Second: Structural risk, being such fires originating in or about the building or a part of the same, as distinct from the contents. Third: The exposure risk, those fires carried by communication from the original seat of fire to other structures. I would class the conditions under which the different kinds of fire occur as follows: First: Cities densely built. Second: Towns, cities and villages, where one or two streets are densely built, and the balance of the community contains structures fairly isolated from each other. Third: Villages, containing risks sufficiently isolated from each other. Fourth: Completely isolated structures, such as manufacturing plants, asylums, hospitals, and all classes of structures built at such a distance from any other structure that in no event can they communicate fire elsewhere. It is self-evident from this classification that cities and towns must provide proper means for the ready control of fire. It is important to know what agencies exist for the control of fire other than the fire departments. The use of the sprinkler systems, which is nothing else than a local water supply in a structure, which is automatically brought into operation when a certain degree of heat is attained, is an important factor in the prevention of serious fires. The increasing efficiency of the sprinkler systems in the protection of buildings, and their contents, from loss, and the automatic extinguishment of fires through their agency, is a feature of distinct economic influence; it is especially so in the case of isolated plants, and is the best single means of protection that can be afforded. Its auxiliary work for firemen is of no less importance, and the frequency with which fires have been held in check, and remained within the control and easy extinguishment by firemen upon their arrival, makes the use of sprinkler plants a matter of much consideration in the protection of structures in our larger cities, irrespective of the excellence or proficiency of the departments therein.

The maintenance of special and direct wires to buildings to communicate alarms of fire facilitates the work of the department, and this feature of the use of the telegraph system is growing. Stationary fire appliances have not secured the respect of professional firemen. I believe that the largest cause of failure in stationary appliances is due less to the appliances themselves than to the fact that it is expected to use them efficiently with untrained help, and without having them under that regular inspection and preparation which is essential for all appliances that relate to fire. I think that the stationary fire appliances, without reasonably efficient and trained help to use them, will remain, therefore, of uncertain value, if not of actual detriment in the attempt to control fire.

The importance of locating a fire is one that strikes the mind of every experienced fireman instantly; and no fireman can claim thorough competency, unless he acquires and trains himself to the knowledge or art of discovering the exact location of a fire. This is his first main reliance toward the actual control. I trust no one will imagine that he is to look for the starting point of a fire if, upon his arrival, he finds the building on fire from cellar to roof. It certainly must be clear to all of you how essential it is, in order to secure the

* An address delivered by Simon Brentano, at the twenty-fifth convention of the International Association of Fire Engineers, held at New Haven, Conn., August 17-20, 1897.

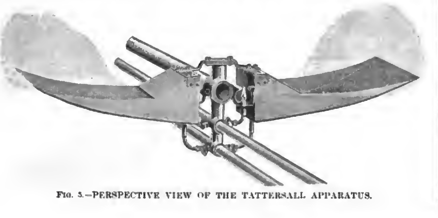

FIG. 5.—PERSPECTIVE VIEW OF THE TATTERSALL APPARATUS.

best results, to be able to promptly locate fires. The next object in the control of fire is the proper location of companies, and assignment of officers and men. It is not my purpose to go into details and describe the operations of a fire. My main point is to establish that the rules for the control of fire must be uppermost in the mind of any one who hopes to achieve success in this direction. Some men who are successful, but who have never analyzed their methods or operations at a fire, assume that no thought or reflection is necessary. These men are fortunate in the sense that they generally exercise a correct and instant judgment, but, notwithstanding their apparent lack of deliberation, their plans and conclusions, no matter how quickly formed, are subject to a careful analysis. The danger existing in every fire, however minute, is the generation of heat and gas. It is a matter of the highest importance to remember that the process of combustion at fires causes an abnormal condition of the air surrounding the fire. The air certainly becomes changed by being charged with the heat and gases of combustion. It takes on altogether different qualities, and what these exact qualities are, and how they differ at different fires, is as yet unknown to anybody. From observations made at numerous fires, I am convinced that the atmosphere at certain stages of a fire, and especially certain parts of it, is transformed into a combustible and explosive gas, and I believe that this air is a means of actual communication of fire. By a school of writers on this subject, who have made some observations, it is believed that the air or gas is caused in a large measure, if not entirely, by reason of the water used for the purpose of extinguishment being decomposed into its original elements of oxygen and hydrogen, and that the hydrogen is the agency which communicates the spread of fire. I am convinced, on the other hand, that in the entire absence of water, this superheated air or gas accumulates, and is a dangerous agent in the dissemination of fire, and the longer a fire remains without control, the larger the quantity of air that becomes heated in this manner. Indeed, the danger of destruction to any considerable area arises in my mind from this source, since the communication of fire through this means is far more rapid than can be the control over the new territory which it has invaded; hence the extreme danger from this cause. In every fire the gas or superheated air is generated to a certain amount, and you all have experienced this, perhaps, and some of its manifestations. These consist of back draughts, the raising of roofs, the explosions in buildings, with sudden collapse, and even the superheating of air in the buildings adjoining those on fire, causing explosions, and often resulting in fire. Nothing is more essential to the control of fire than the elimination, so much as may be possible, of the chances for the accumulation of large bodies of this air or gas. Of course, the earlier a fire is controlled, the less opportunity exists for its formation.

On the subject of the control of fire, I shall now repeat, in part, the matter which I have used in a paper read before the Massachusetts State convention.

It is the modern fireman who was instrumental in affording the means and devising the methods whereby a fire is controlled. The old methods believed a fire destined to have its own way unchecked. The modern system has for its object, and succeeds in most instances, indeed, in the great majority of cases, in keeping a fire within reasonable control. What do we actually mean by the control of a fire? I define the control of a fire to mean its restriction as nearly as may be possible, under the varying circumstances attendant upon and surrounding each fire, to the actual point of origin, or to keep it within that boundary which the fire has attained at the time of the arrival of apparatus. In some instances this means that the fire will be confined to the room and to the actual incipient blaze which ignited a window curtain; in others, it will mean the complete destruction of the building in which the fire originated; again, in others, it may mean the ignition and destruction of neighboring and adjacent buildings. But at no time has the experienced fireman lost his sense of control, nor have his plans changed, except by reason of those changes forced upon him by the apparent gain of the fire over all control for the time being. But in such cases companies are assigned to new positions, the lessening points of danger abandoned, the more menacing positions strengthened, and that disposition is made in detail that evinces the sagacity, the quick and ripened judgment of the fireman, and that throughout illustrates the underlying object to be achieved, namely, the control of fire. Against what fearful odds the control is often won is familiar to you all. It must often have impressed itself upon your minds, reflecting on the changing conditions that have existed during the course of some of the fires at which you have performed duty, how the careful assignment of one company may have been the key point, or in other words, determined the control of fire. The control of fire should not at any time be confused with the actual extinguishment of fire. I have seen fires far more destructive than the occasion warranted, by reason of the fact that the proper estimate was not placed upon the chief element attaching to every fire, namely, a correct judgment as to its control. To illustrate this by familiar example, I need only point out that many fires gain and cover an area larger than they should, because upon arrival the companies, or those in charge of them, fail to recognize that the original point of fire is beyond instant control, but in the mistaken effort to extinguish this original source of fire, instead of keeping it in check, it permits the fire to extend.

The inability to view a fire and to determine at once whether or not the greater effort should not be extended to surrounding risks rather than the immediate fire itself, forms one of those errors of judgment in practice which has been, and will continue to be, a serious cause of unnecessary fire loss. Of course the control of a fire, I need not say, should be effected with the greatest celerity possible. It is, of course, a simple and fundamental law of fire extinguishment that the danger of destruction is lessened with each moment gained in the control. Most fires attain their maximum in relatively short time. I have timed several very serious fires, and I have estimated that they have reached their maximum danger point in thirty five to fifty minutes. After that time the fire was a receding one; that is to say, the control over it was becoming manifest. A fire which, one hour after its inception, is burning as fiercely or as dangerously, and shows no sign of abatement, is a most serious fire, and portends great danger. Of course, I except from this classification structures completely isolated, certain oil fires and lumber fires, but in the main the visible signs of gain should be present in thirty-five to fifty minutes. I have seen a very dangerous fire in a five story building, about 50 × 75 feet, where the fire originated on the third floor, and at once assumed large proportions, controlled in exactly fourteen minutes, although the actual duty of fire extinguishment kept a sufficient number of companies busy for five hours subsequently. The great Bleecker Street fire in New York, which I consider to have been one of the most dangerous fires that have occurred in that city, reached its greatest danger point in forty minutes after the first alarm had been sent out. After that period of time, further danger to surrounding property was passed. If you will accustom yourselves to make some calculations as to the time of control of most fires, I am sure you will often be surprised at the quick mastering of the maximum danger. I again repeat my injunction to separate in your thoughts the method of control, and the attainment of its object, from the mere act of fire extinguishment. In many fires the matter of control and extinguishment are performed simultaneously. In many and in most serious fires the control of a fire, of course, precedes its extinguishment.

I will now allude to another simple law in fire extinguishment. It has no merit of novelty, but it has the distinct advantage of being permanently associated with any successful achievement in fire practice. The rule is one perhaps sufficiently known. It is this: Bring your water to bear as near as possible to the actual seat of fire or seat of combustion, if you expect the most successful results. It requires a specific amount of water to destroy the heat units generated by combustion; the exact amount of water to apply is, and must remain, an unknown quantity, because different kinds of fires develop different degrees of heat or develop a more intense flame at certain stages of the fire, then often the heat units at one point of a fire are enormously intensified when compared to other portions of the same fire. Accordingly, in the actual practice of fire extinguishment there is a great loss in the economical use of water, since no standard can be fixed which will make a working rule. The most efficient use of water is attained when the stream is directed at a range as close as practical conditions permit to the actual seat of fire. The waste of water is less blamable than the waste of a company's strength, which fail to use their stream or direct it to that part of a fire where it will do the most efficient service. Firemen often continue to play upon certain portions of a fire not reaching the vital part at all, or what is equally faulty, will maintain their stream constantly in the same position, when the condition which has warranted that position has passed away, and when they should have passed away with it to another point. Firemen should be reminded that a stream of water will not yet readily penetrate solid brick walls, and that every attempt should be made from the first second in taking position to make their streams effective, and to see that streams are not interrupted in their course. In this connection I allude to another law of fire extinguishment, familiar to all, that the efficiency of a fire stream is dependent in a large measure upon its volume and force; these two elements together constitute the highest efficiency of fire streams, not alone its volume, but its force of penetration. The particular reason, and there exists one, why the quality of force or pressure, as we denominate it, should have such an important influence in extinguishing fire, I am not yet prepared to assign. I do think that certain great and influencing results follow from a stream being directed with pressure, which do not take place when the same volume of water is used without that pressure. Firemen should familiarize themselves with the proper size of nozzles to use with certain pressure, and have at all times ready command of that knowledge which will enable them to secure efficient streams.

I now come again to an important point essential in the primary education of every fireman. I refer to the ability to promptly locate a fire. The term "locating a fire" means in this sense the requisite and immediate knowledge to ascertain the actual point of a fire in structures where a fire is burning, but of which the actual seat is not easily discoverable, or has not made itself manifest. We are familiar with the many fine fires traveling away from the starting point and revealing themselves so far from the fire that, unless skillful judgment is used, and quick work accomplished, the fire may appear to be extinguished, and yet the actual cause and greater fire remain unextinguished. The same suggestion applies to other fires, when buildings are heavily charged with smoke and heated gases, and where it is almost useless and indeed dangerous to start a stream until a fire has been located. The miscellaneous crowding of companies into a charged building before a fire is located is bad fire practice, and unnecessarily jeopardizes the safety of the men.

I shall touch briefly a recent development which I have noticed with some regret, and which, I believe, can with propriety be mentioned here. I allude to the greatly improved apparatus and implements which are coming into the service of firemen, but which, unfortunately, have imbued some firemen with the idea that they need never use their own brains hereafter. To those firemen relying so largely upon apparatus instead of their own minds for successful work, it is only necessary to remark that the appliances, after all, cannot supplant or make up the deficiency in human intellect.

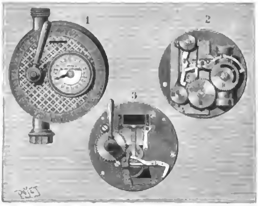
In expecting to exercise a control of fire, every fire official must bear in mind, according to the department with which he is connected, the hazard and menace which a community can be exposed to, when two or more fires occur concurrently. His provision for assignment of companies, and for the prompt relief and return of companies to quarters if not absolutely necessary at a fire, should be constantly before him.

Upon the safe protection, immunity from and ready control of fires depend the prosperity, the importance, and the happiness of a community, as much as it does upon any other department of the municipal service. Surely this will be conceded upon a little reflection.

While extending protection against fire, and aiming at the better and quicker control of fire, it is no less the duty of the fireman charged with such responsibilities to persistently, honestly, and fearlessly awaken and maintain a public interest in all that relates to his art, to the end that sufficient means are placed at his disposition to enable him to perform his duties, and to enlighten the public mind to the fact that the work of a fireman is one requiring the exercise of correct judgment, experience, skill, and other attributes, and withal a combination of such qualities that forbid the appointment or engagement of men in any capacity in our fire departments, unless they possess the qualities demanded. This is a duty that firemen owe to themselves, to their communities, and to the public at large.

THE AUTOMATIC GAS DISTRIBUTER.

THE Hour automatic gas distributer represented herewith is really a meter, but one that allows only a definite quantity of gas to flow, corresponding to the value of the coin for which it is constructed. The occasional purchaser who, through his franc or fifty centime piece, has acquired the right to burn that much money's worth of gas, regulates his consumption at his will and lights or extinguishes the gas whenever he chooses. It is possible for him at any instant to read upon a dial divided into fractions equivalent to five centimeters' worth of gas what remains for him to use.



AUTOMATIC GAS DISTRIBUTER.

As for the operation of the apparatus, that is very simple. As long as no coin has been introduced into it, the external handle is loose and disconnected with the cock that allows the gas to flow. In order that the would-be consumer may obtain a supply of gas, it is necessary for him to insert a coin of the requisite value into a slot provided for the purpose. The coin, in falling upon the lever, L, Fig. 3, depresses the latter and establishes the necessary connection between the cock and the handle. All that the consumer then has to do is to turn the latter in order to open the former. But, while doing this, he sets a spring, which, as soon as the quantity of gas paid for has made its exit, will suddenly interrupt the junction and close the cock automatically.

The simple opening of the cock suffices likewise to wind up and set a small clockwork movement in operation. A cam, C, Fig. 2, is carried along by the movement, and after finishing its revolution, frees the spring just as the last of the quantity of gas paid for is flowing out. At the same time, the coin falls into a drawer in which the receipts are stored. The lever, L, rises, and all interdependence between the handle and the cock ceases.

As may be imagined, the rotary speed of the cam must at every instant be proportional to the quantity of gas that flows out, and consequently, to the opening of the cock. This is regulated and the necessary acceleration or retardation of the clockwork movement is produced by automatically modifying the length of the pendulum. To this effect, the bob, H, of the latter slides upon its rod, thanks to a small chain from which it is suspended and that is carried along by a sector, S, pivoting upon the shell of the cock.—La Nature.

The Hungarian government has completed the necessary arrangements for the construction, without delay, of a subway beneath the Danube at Budapest on the same principle as that of the new Blackwall tunnel under the Thames in London.

SUBMARINE TELEGRAPHY—A NEW FRENCH TRANSATLANTIC CABLE.

By HENRY HAYNIE, in Boston Herald.

ANOTHER transatlantic cable is being laid from France to the United States, and very soon the French company will have two lines running under the ocean from the village of Orleans, Mass., on old Cape Cod to the city of Brest in ancient Brittany. It is not every one who can remember the earliest days of Atlantic telegraphy, that is to say, when a cable was laid from the shores of Newfoundland to the coast of Ireland, and when President Buchanan exchanged messages with Queen Victoria.

In 1879 the French republic, or rather M. Pouyer-Quertier and his friends, wanted an Atlantic cable to "secure the telegraphic independence of France," as another one, laid some time before from Brest, though undertaken on the principle of competition, had been absorbed by the Anglo-American. M. Pouyer-Quertier was minister of finance under President Thiers, and he played a prominent part in arranging for the indemnity of several billions of francs paid to Germany. Continental capitalists backed up the enterprise eagerly, but the English opposed it energetically. That French cable was landed first at St. Pierre, a matter of some 2,400 miles from Brest, and was thence continued for a distance of 850 miles more to the east shore of Cape Cod, in Eastham, and an office of transmission was established there. But two or three years back the station was moved to Orleans.

Some 1,223 separate and distinct cables, aggregating a total of nearly 185,000 miles, have been laid throughout the world in less than fifty years, at a cost of at least $165,000,000. However, we hardly ever think of the "thousand and one" submarine lines that cross coves, bays, estuaries, wide rivers, seas between islands, etc.; when we happen to speak of cables, we usually mean the great Atlantic system of telegraphy. Great Britain owns most of the great cables, operating fourteen long ocean cables, nine of which belong exclusively to her; in the Indias she owns ninety three, and has a part ownership in five more; her home system includes 102 separate lines; and in her colonies there are forty-five, making a total of 260 cables. France operates sixty-five separate ocean cables, many of them the most important in existence. One of these is the French cable, as it is familiarly called, that has been working from old Brittany to old Cape Cod these eighteen years. Germany has forty-five cables, but they are short in comparison with those of England or France. Italy has thirty-eight. There are more cables in Sweden-Norway than in any other country, but they are all very short ones.

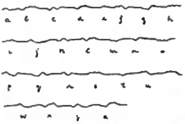
A new board of directors, under the management of M. Depelley, determined a short while back to improve the French Cable Company's facilities by reinforcing their old cable by another, and it is this new one which is now being laid. It is made up with the largest conductor ever yet laid to the United States, and it will be completed before the dead leaves finish falling. It will parallel the route of the old French cable, but so large are the dimensions of the core conveying the current that it is expected the message from France can be freely read off the siphon recorder here in Orleans without having to be written down and retransmitted at St. Pierre. The size of this coil is 700 or 800 pounds to the mile, independent of the gutta percha insulation, the manila covering and the further covering of large steel wires to protect it from material injury. To lay such a cable requires a steamer of extraordinary dimensions equipped with all kinds of electrical apparatus, as well as the most approved gearing and machinery. So the French company secured the steamship Silvertown. She is 350 feet long, 55 feet broad, 34 feet in depth, is fitted with engines of 1,800 I. H. P., and steams 10½ knots an hour, with a consumption of 30 tons of coal daily. She carries three tanks, each being 32 feet deep, and the largest is 58 feet in diameter. This tank has, consequently, over 70,000 cubic feet capacity.

When carrying 6,390 tons, the draught of the Silvertown is 28 feet. The coal bunkers have a capacity of 1,300 tons, besides which 1,000 tons of fuel can be stowed in the forehold. She has taken on board at one time as much as 2,160 knots of ocean cable. But a cable of the proportions now being laid down by the French company calls for three or four trips to complete the work. When the Silvertown pays out all the cable on board, her crew attach the end to a buoy and drop it overboard. Then she steams back to France, where the cable is made, takes on a further supply, returns to this buoy, takes up the end, makes a splice to it and so continues the work until the cable is entirely laid from Brest to Orleans.

The story of how a lost cable or a non-working one is picked up in midocean has been told repeatedly in newspapers and in magazines, but not so of the scene in a coast station where operators have to wait patiently and may be a long time for new connection with the office at the thither side of the Atlantic. The last important break in the French cable occurred last October, and it produced a delay of three weeks. "Day after day, night after night, through several weeks," said an operator to me, "one of us was always on duty watching and listening until sight and hearing were almost gone. Thrice every day and twice every night the wire was tested, not with any expectation of a message from our comrade on the steamer—it was not yet time for that—but simply to keep an accurate record of the condition of the cable. Sometimes wild messages seemed to be coming from the deep, extraordinary cablegrams in a language of gibberish that was wholly incoherent, but these were merely the results of magnetic storms and earth currents which reflected the galvanometer rapidly or jerked it to flash sentences that were nonsense. Then one morning at the end of three weeks the operator on duty observed a peculiar indication about the instrument which showed his experienced eye that a message was at hand, and in a few moments we were in communication with midocean."

The French Cable Company is represented in the United States by Mr. M. Laricenne, at New York, while the superintendent or manager of the Orleans station is Mr. H. Osborne, an Englishman, who learned how to telegraph when a mere boy in his first school days. The present writer is indebted to the latter for much valuable information. At the time of one of my visits to his office a cablegram from Father Neptune was received and handed to me. It is reproduced on this page precisely as it was traced by a curiously shaped glass pen worked by a delicate galvanometer on "the tape" or white paper string about three-quarters of an inch in width.

The cable men handle all the cable work, and there is a countercheck or record kept of all their work by the land wire men. The cable pen waves off a message, and above the line of curious looking ups and downs and curves which a delicately poised indicator traces stretches another line of words, but their lettering is broken into dots and dashes. This upper line is written by the Morse system of telegraphy, the lower or real cablegram is woven by a curiously shaped thing of hol-

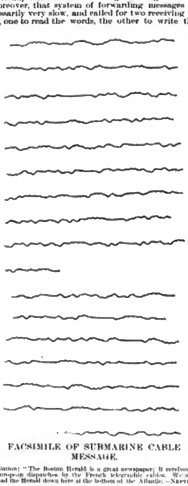


THE SUBMARINE TELEGRAPH ALPHABET.

low glass, through which flows a dark liquid, and the pen is caused to move or waver by the feeble electric current passing the galvanometer at the right hand of the operator. This instrument, the invention of Sir William Thomson (now Lord Kelvin), took the place of the much talked of and written of spark or flash telegraphy some time back.

I do not know whether any of my readers have seen in practice that old fashioned mirror system of cabling, as it was called, by which they communicated formerly across the Atlantic. If they ever visit a cable station I strongly recommend them, as a matter of curiosity, to see it, if possible, for, though no longer in use, I dare say the manager will have it in storage somewhere about the office. It is one of the most ingenious pieces of machinery that I have ever beheld, even if it is obsolete. It involved this: The continual watching of a small speck of light reflected from a tiny mirror and traveling over a diagram representing words or letters of the alphabet or something of that sort. Naturally, the strain on the eyesight was immense; it was so great, in fact, that after some years' exercise of it a man became almost absolutely incapable of turning his attention to any other mode of earning his living.

Moreover, that system of forwarding messages was necessarily very slow, and called for two receiving persons, one to read the words, the other to write them



FACSIMILE OF SUBMARINE CABLE MESSAGE.

Translation: "The Boston Herald is a great newspaper; it receives long European dispatches by the French telegraphic cables. We always read the Herald down here at the bottom of the Atlantic.—NEPTUNE."

down as called out to him. The companies, as well as the operators, were glad, therefore, when Sir William's invention enabled them to make use of the present system. If Morse signals could be sent by sound under the Atlantic, transmission of dispatches would be made more quickly and of course at less expense than is now the case. When the first submarine cable was laid under the ocean such sounds did work feebly through the line at the rate of about three words a minute, I believe, but that was altogether too slow, and was uncertain; so another method had to be invented. Thus came into existence what was known as mirror and flashlight system, just now spoken of. While it worked much more swiftly than the Morse, it could do no more than twelve to fifteen words a minute. This slowness impelled inventors to devise something else, and finally Sir William Thomson got up the present system, which is good for forty to forty-five words a minute. But attention is being constantly directed toward the utilization of sound signals by cable companies, and success will probably come eventually, though it is not yet in sight by any means.

Messages have been sent thousands on thousands of miles with wonderful swiftness. For instance, the London Globe of March 23, 1893, printed the following paragraph: "The result of the university boat race was telegraphed and received in New York three seconds after the result was known at Mortlake. This was accomplished by the French Atlantic Cable Company, and is one of the smartest telegraphic feats on record."

At the time of our presidential election in 1892 an English newspaper published in Kobe, Japan, wanted the result as soon as known in New York, and the editor arranged by correspondence with the manager in America of the French cable to forward the same as swiftly as possible. I may say that when it is midnight in New York it is only 2:15 o'clock of an afternoon at Kobe. Well, at midnight of the day of election these four words: "Herald, Kobe, Japan, Cleveland," were started from the office in Gotham. They went to Cape Cod, thence to St. Pierre, thence to Brest, thence to Paris, thence across the continent of Europe, under the Mediterranean to Africa, under the Red Sea to Asia, then through India and China, under the Sea of China to Yokohama, from which place they were telegraphed by land wires to Kobe, where they were handed to the editor, who at once put the Herald with the important news to press, and an "extra" was selling in the streets of Kobe at 4:30 o'clock. Precisely two hours and fifteen minutes had elapsed since that dispatch left New York, and I daresay as much time was consumed in getting it from Yokohama to Kobe, setting it up in type, and printing it as there was in transmitting it from the United States to Japan.

It is not so very far from here to Boston, straightaway, but as yet cablegrams from Europe addressed to your city are not sent directly there. In the summer of 1895, while in Portland, Me., I had occasion to send a telegram to Bar Harbor, some distance to the east-northeast from that place. When the message was handed in and paid for, the gossiping clerk said it would have to be sent to Boston first before it started on its way to Bar Harbor. This, I thought then, was quite a "roundabout way" of reaching that resort; but it was a mere nothing as compared with the flight of a telegram from Orleans to Boston. All messages from Europe are distributed only from the New York office, so I was informed at the cable station. It is the intention to open a cable office in Boston soon, and before this is done a land wire will be constructed from this village to the capital of the commonwealth; meanwhile all dispatches must go to the metropolis. We will suppose that Ambassador Porter wants to communicate with the editor of the Boston Herald. He files his message in one of the many telegraph bureaus that are scattered over Paris, and it starts on its long voyage straightaway to America. The course is due westward to the island of St. Pierre-et-Miquelon, off Newfoundland—owned by the French republic; but thence the submarine cable runs southerly to Cape Cod and finally reaches Orleans, about 65 miles from Boston in a direct course. Received there and recorded, the diplomatic communication to our fourth estate is not, however, sent directly on to its destination. Instead, it takes its way the whole length of Cape Cod to the mainland of Massachusetts, goes out of that State into Rhode Island; out of that and into Connecticut; thence into New York State beyond Stamford, and, by and by, reaches the island of Manhattan, where another record and transfer are made of the message. This done, it is "rushed" toward Boston. Again it travels in four States, and finally, after having been flashed along something like 500 miles of land wire since it came ashore at Orleans, it reaches its destination in the Boston Herald building.

This "circumlocution" and its attendant delay, not to mention the annoyance of being thus compelled to be subordinate to Gotham, will disappear altogether when the French company opens its Boston office, and enters into competition with the Commercial, the Western Union, the Anglo-American, the Direct and all the other lines. For though the rates are precisely the same on all of them from Boston to Paris or to London, there is competitive rivalry, and business is keenly sought for by each company. Said the manager:

"Though I cannot reveal to you any details in the commercial transactions of this company, I may state that our traffic has not materially suffered from the recent business depression, and I think we have had a fair share of the messages between America and Europe, both ways. Our precise percentage of the entire traffic as compared with the percentage of it which the Anglo or some other company secured is an office secret, but I repeat we have no reason to complain; quite the contrary, in fact. When the new cable is down, when we have our own office in Boston, and a land wire thence to this station, our share of the whole will be considerably increased, while the public and the press will have a much better service than ever."

The first charge for messages through the Atlantic cable, from New York to London, or vice versa, was $100 for 20 words; this rate was reduced after some time to $50 for 10 words, and by 1875 the tariff had got down to $1 a word. A new company completed a cable in 1875, and then a rate of 75 cents a word was established. The French Cable Company—Le Compagnie Francaise du Telegraphe de Paris à New York—landed its cable on the shore of Cape Cod in 1879, and effected a reduction of tariff to 50 cents; it is now 25 cents a word to either London or Paris.

But the cost of cabling a dispatch to some place in Japan or China, or, indeed, to any country on the western coast of the Pacific Ocean, would be very great. The message would have to be sent over 3,000 miles due east before it could commence feeling its way toward Japan or Australia. Such a dispatch sent from San Francisco would have to cross the American continent,

the Atlantic Ocean, Europe, a part of Africa, and all of Asia, together with numerous intermediate seas and other oceans before it reached Yokohama or Melbourne. The cost per word would be as much as $2.35 to Auckland, or $2.35 to the capital of Japan.

THE MASSENA WATER POWER ELECTRICAL GENERATING PLANT.

In our issue for August, says the American Electrician, announcement was made for the commencement of work on the canal of the St. Lawrence Power Company at Massena, N. Y., and we are now enabled to

FIG. 1.—SECTION OF CANAL.

give an account of some of the more important features of this great undertaking, which involves the immediate utilization of 75,000 horse power, with a prospective utilization of 150,000 horse power.

Fig. 5 is a map showing the location of the plant and canal and Fig. 1 is a section of the latter. The St. Lawrence River has a fall of more than 50 feet over the Long Sault rapids between the mouth of the canal and the point where a small stream—the Grass River—flows into the St. Lawrence. The canal will connect the St. Lawrence with the Grass River at a point of the latter where the water will have a fall to its bed of 47 feet, of

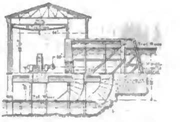


FIG. 2.—SECTION OF POWER HOUSE.

which there will be available at the turbines an effective head of over 40 feet.

The power house will be built on the bed of Grass River below the canal outlet, and will be 600 feet long by 130 feet wide. Fig. 4 shows a plan of the power house and Fig. 2 a transverse section. The turbines will be of the horizontal shaft type, two to each shaft and each pair developing 5,300 horse power. Fig. 3 shows the setting of the pairs and the draught tubes.

The turbine shafts, which are 80 feet long, will extend through a wall separating the canal or turbine chamber and the power house. Each shaft will have mounted

FIG. 3.—ARRANGEMENT OF DYNAMOS AND TURBINES.

on it a great ring of steel, which will carry on its circumference twenty external pole pieces, the ring and pole pieces being of one solid casting of steel. The former will have an extreme diameter of 15 feet and be about 3 feet wide and supported by a massive hub having ten radial arms or spokes. Each of the machines will weigh 350,000 pounds, stand 22 feet high above the top of the foundation and occupy a floor space of 22 feet by 18 feet.

The stationary part of the dynamo will form the armature and will consist of a large ring or cylinder, the inner surface of which will be made up of plates of soft, thin steel on edge held by the massive outer ring of cast iron. The inner surface of the steel plates will have slots in which will be laid copper bars parallel with the shaft of machine, insulated from each other with mica and in which will be generated the three-phased currents.

The poles of the revolving portion or field of the machine will be wound with copper ribbon. The speed will be 180 r. p. m. and the current will be generated at ...quency of 30 periods per second.

...e owners of the St. Lawrence Power Company are ...s. Stewart & Company, 40 Wall Street, New York. ...ngineer is Mr. John Bogart, formerly New York ...ngineer.

...racts for construction of the plant have been let as follows: For excavating the canal, building the power house and hydraulic work, to the Lehigh Construction Company, Limited, of South Bethlehem, Pa.; the fifteen 5,000 horse power generators will be furnished by the Westinghouse Electric and Manufacturing Company; and the turbines by the Stilwell-Bierce & Smith-Vaile Company, of Dayton, O. Seventy-five thousand horse power electrical energy are to be available before the end of next year.—American Electrician.

THE MAGNETIC DIP OF ANCIENT TERRA-COTTAS.

The article on this subject contributed by the Cavaliere Giacomo Boni to the Journal of the Royal Institution of British Architects, June 17, 1897, is of great importance, says the Builder. Dr. Folgheraiter's experiments have proved that clay cylinders acquire during the period of cooling after being baked a permanent magnetism, owing to induction by the earth's magnetic field. If we know the position in which a terra-cotta vase, for example, has been baked and determine the direction of the field of its remanent magnetism, then we know the "dip" of the earth's magnetic field at the period at which the vase was baked. If we know the "dip," then, as it is always slowly changing, it will be a great help in fixing the date of the vase. Conversely, if we know the date of the baking and the position in which it was baked, then we can find the "dip" at that period. Prior to 1570 we have no records of the magnetic "dip." Since that date it attained a maximum value of 74° 42′ in 1720, and then gradually diminished to its present value of 67° 30′. Dr. Folgheraiter found that four terra cotta cistae of about the eighth century B. C. show distinct traces of south polarity about their bases, which is strong evidence that at the time and place where these vases were baked a magnetic needle would have dipped toward the South Pole. The Cavaliere Giacomo Boni points out the necessity of further experiments in this direction. He suggests that brick walls which have been subjected to fire at a known date, e. g., the great council hall of the ducal palace in Venice, burnt A. D. 1575, should be examined for traces of remanent magnetism. If we can thus determine approximately the "dip" at the period of the fire, it will be an obvious example of the value of the method. A more promising suggestion is to examine magnetically volcanic rocks due to eruptions of historical date. At Herculaneum, for example, there must be plenty of strongly magnetic substances which came in contact with the lava, by examining which the magnetic dip at the date of the eruption might be ascertained.

Members of the Royal Institution of British Architects are asked to give notice of any buildings they may happen to come across which exhibit traces of magnetism induced at some former period. In a note Dr. Folgheraiter's method is described, presumably for their instruction. It is very difficult for any one but an expert on laboratory methods to understand it. It is of no great use, except as a laboratory method of determining the magnetism of something like a vase uniformly magnetized. The mysterious "arctg." mentioned is a misprint for "arctg.," or, as we write it in England, tan⁻¹. From experiments of our own on a block of asbestos, afterward found to contain traces of magnetite, we found that it was very irregularly magnetized; the lines of force seemed to radiate in all directions through the body. Baked clay, we imagine, contains considerably less than ten per cent. of the ferrous ferric oxide, which constitutes its magnetic substance; it will, therefore, be a very feebly magnetic body, and it will be very difficult to determine the direction of its remanent magnetism, especially if it is not uniform.

Electricians can determine to within one per cent. the strength of the current in an electric cable by means of a little compass, such as is often worn as a "charm" on a watch chain. Architects often use such a compass to determine the position of an iron girder or a gas pipe. A sensitive compass on this principle might be employed to detect whether there is anything abnormal in the magnetic field in the neighborhood of an old building or a monument. An expert could then find out the cause of this, and, if possible, determine the direction of the feeble remanent magnetism. It is highly probable that some curious instances of magnetic effects might be discovered by this means, if several people systematically experimented with this end in view. At any rate, speaking from experience, we can say that it is no waste of time to learn how to use a charm compass scientifically.

A NOTE ON SOME OF THE REQUIREMENTS FOR A SANITARY MILK SUPPLY.*

By WILLIAM T. SEDGWICK, Ph.D.

It is now generally recognized that the milk supply problem is one of the most pressing in American sanitation, and I am frequently asked to give an opinion as to the merits of this or that remedial measure. I have therefore thought it worth while to lay down very briefly, but I hope clearly, the fundamental principles which must be carefully kept in mind in seeking to introduce sanitary reforms into this important industry.

The fundamental, indispensable and all-controlling requirement of a sanitary milk supply is that milk, when consumed, shall be as nearly normal as possible. Normal milk is milk as it flows from the mammary gland of a normal animal, and a normal animal is obviously one that is healthy and well fed. From such an animal under normal conditions the milk supply of its young passes almost instantaneously, and without exposure to dust and air, from the milk ducts of the mother to the stomach of the suckling. Such milk is absolutely fresh, warm and free from dirt. It is not only undecomposed, but nearly or quite free from the germs (bacteria) of decomposition.

Ordinary city milk, on the contrary, is neither fresh, warm, nor free from dirt, and if not already far on the road toward decomposition, is always richly seeded with bacteria. It is not always derived from healthy or well-fed animals, and is seldom drawn under clean and sanitary conditions, so that even at the outset it may be, and often is, very far from normal. It is also too often transported over long distances, so that it still further loses its original freshness, and it is frequently manipulated by unclean, and sometimes by diseased, workmen. By the time it reaches the consumer, therefore, it is not only no longer normal milk, but usually stale, dirty, more or less decomposed, and sometimes also diseased.

Some of the steps to be taken in securing a more sanitary supply are easily deduced from the foregoing facts, and are as follows:

1. Milch cows should be healthy, well fed, well kept and well cared for.

2. Milk should be derived from such cows only, and with all possible precautions in regard to sanitation

* From the Technology Quarterly of the Massachusetts Institute of Technology.

and cleanness. Cows as sources of food should be tended as carefully as or more carefully than horses used only for burden or pleasure. The operation of milking should be looked after with special care. Above all, the hands of the milker should be carefully washed just before he begins to milk, his own personal cleanliness being even more important than that of the cow.

3. When drawn, milk should be immediately filtered and chilled, as means of retarding decomposition, and all articles with which it comes in contact, such as filters, pails, cans, etc., should be scrupulously clean.

4. The milk thus prepared should be delivered, if possible, at once.

5. If it is impossible to deliver the milk immediately, it will be impossible to deliver normal milk, and such milk cannot, in fact, generally be obtained in cities. The best that can be done, probably, is to deliver as speedily as possible two kinds of milk, viz.:

(a) The milk thus far described, kept as nearly normal as the conditions will allow.

(b) The same milk carefully pasteurized either (and preferably) on the farm where it is produced or at some central point accessible from a number of farms, or, if this be impracticable, at some good distributing point in or near the city to be served.

The former (a), which may be called "chilled milk" or "raw milk" or "ordinary milk," will be preferred by some. The latter (b), which may be called "pasteurized milk" or "sanitary milk," will be preferred by many as being certainly free from the germs of infectious disease.

There can be no doubt that any individual or company which honestly strives to displace the present highly objectionable milk supply of American cities by a supply such as has been here described deserves, and will secure, the support and the confidence of the more intelligent portion of the community.

THE PARIS INTERNATIONAL EXHIBITION OF 1900.

THE preparatory work of a great international exhibition like that which is to be held in Paris in less than three years is as interesting as its ultimate installation. Not the least considerable of these preparation works are the many buildings of all kinds in which exhibits will be placed; the extensive works which have to be carried out to facilitate the convenience and circulation of visitors; and the complicated organization necessary for the transport and handling of exhibitors' goods and cases. Progress has sufficiently far advanced to enable us to take some note of the first named preparations. The various works of demolition are being actively pursued, among them especially the central dome in the Champs de Mars, of which the steel framework is being removed girder by girder by means of a timber staging about 300 ft. in height, erected inside the building. This staging has been constructed with a clear internal space to facilitate the lowering of heavy weights, one of which is the gigantic statue of repoussé zinc which stood on the summit of the dome, and the weight of which is about 9 tons. The removal of the Palais de l'Industrie is also rapidly progressing.

The new constructive works are advancing, although at present they are chiefly limited to foundations of the new palaces; at the same time the architects of the two Fine Arts buildings are constructing plaster models of them, one hundredth full size. By means of these models it will be possible to form an exact idea of the architectural effects and decorating details, and to introduce any changes or modifications before the buildings are actually constructed. It is considered that the expense thus incurred will effect considerable economy in the end, and that the definite results must be more satisfactory. The models are well advanced toward completion, and the contract for the main façade of the principal palace has been let. It is a heavy undertaking and will cost at least a million and a half francs. One of the most interesting features at the present time is the preparatory work for the new bridge over the Seine—the Pont Alexandre III. Already the quays on each side of the river are opened up and excavations for the abutments are in progress. The inclosure of sheet piling on the right bank, within which the foundation caisson will be placed, is almost completed.

The erection of the caisson is well advanced. The method of building the foundations is by compressed air. These foundations will be actively pushed forward as soon as the air conduits are laid, and it is an interesting detail that the supply will be furnished from one of the mains of the Paris Compressed Air Company. As for the superstructure of the bridge, the designs are now completed and the whole work will be offered for contract in the course of the present month.

As we said above, the constructive works connected with the 1900 exhibition are of great interest and almost of infinite variety. Even the very temporary buildings forming the engineers' offices connected with the Alexandre Bridge possess some features of interest; they are of iron, the framework being covered by stamped plates of such a form that when put in place a continuous air space is provided between the inner and outer walls. This arrangement has already proved effective in periods of great cold or intense heat, while later on, when it is necessary to remove the buildings, the work can be completed with great expedition. Of a more important character than these temporary offices are the structures intended for the various bureaus of administration, executive, and architecture, preparations for which are now being made on the bank of the Seine, between the Champs de Mars and the Esplanade des Invalides. Some old structures without any actual use, and of which many are to be found in Paris, are to serve for these offices; they are the buildings known as the Ecuries de l'Alma, the sumptuously fitted up range of stables which at one time accommodated the horses of the Emperor Napoleon III. While part of these stables are being transformed into offices, it is also necessary to construct new buildings in the courtyards. A difficulty, however, was found in carrying out this work. The banks of the Seine are formed of stone and earth filling, resting on fine sand, easily washed out during periods of floods. Just where the new office buildings have to be erected this sand is particularly without consistence, and is absolutely unsuitable for foundations; at a relatively considerable depth, however, a solid stratum exists. In order to adapt the ground a new and very interesting system has been adopted—the invention of a well known French engineer, Mr. Louis Dulac. Some time since this engineer, wishing to erect a factory very cheaply, purchased land made up entirely to a depth of about 16 meters of rough filling of all kinds, quite unsuitable for foundations. Mr. Dulac, however, resolved to erect some very heavy structures, 3,000 square meters in area, with walls 12 meters in height and a chimney 30 meters high. He accordingly devised a very simple and inexpensive means of compressing this loose soil and making it suitable to carry the heavy weights just referred to, by means of the device illustrated. The system consists in forming holes in the ground by means of a species of pile driver, the falling weight of which is of the special form shown in the illustration; and afterward of filling these holes with hard material of small dimensions, the agglomeration of which in successive beds provides an entirely satisfactory foundation. The consolidation of bad ground en masse is certainly a novel and interesting idea, and the Dulac process appears to secure this up to a depth of at least 14 meters. To obtain the necessary consolidation of the ground a series of wells are sunk 31 in. in diameter and spaced about 6 ft. apart from center to center; these wells are then filled with lime or cement concrete, which is rammed hard by the falling weight, and form a series of monolithic columns anchored into the ground, the concrete to some extent spreading into the sides of the wells.

In order to sink the shafts, a conical pointed falling weight is employed, which, as will be seen from the illustrations, has somewhat the shape of a large carrot; it weighs 1¼ tons, and falls freely without guides from a height of 10 or 12 meters. It is worked by means of an ordinary piling engine, the frame of which, mounted on wheels, runs upon suitable rails. The falling weight is furnished with a steel point, the upper end has a suspension stem. When the hoisting chain of the piling engine is lowered, a catch with three branches surrounds the head of the weight automatically, and when the chain is raised the jaws close around the weight, holding it fast. As soon as the weight is raised to a certain height the jaws come in contact with a trip gear on the vertical frame of the piling engine, releasing the weight which, falling freely, penetrates 20 in. and sometimes more into the bottom of the well. The process is then repeated, as we have described.

Three types of falling weights are employed, each of them fitted from the same hoisting and releasing gear. The first of these types is the conical form, of which we give an engraving. With this a well 31 in. in diameter can be sunk to a depth of 12 meters in five hours, and the operation so compresses the earth around the well that the latter will hold water when poured into it.

After this the second type of weight is employed. It weighs 1 ton, and has something the form of a shell with its point downward. Naturally, this type is not adapted for boring, but is intended to ram the material that is placed in the well. This material consists of old rubbish, such as broken bricks, etc., in layers, 20 in. or 30 in. thick, alternated with similar layers of béton mixed with hydraulic lime or cement. Each layer is rammed hard by the falling weight, which drives the filling against the sides with the effect that it enters the earth surrounding, and forms a column considerably larger than the diameter of the well. It is, of course, necessary to ascertain whether the column thus formed possesses sufficient resisting power to carry its proportion of the weight of foundations, and for this purpose the third type of falling weight is used. The resistance can be easily ascertained by the amount of penetration into the mass of the column made by the weight falling through a fixed distance a certain number of times.

Where the ground has a sufficient degree of solidity, or where the weights to be supported are not great, the second type of falling weight only is used; with this wells 2 meters deep can easily be bored and the material rammed without changing the weight. In ground possessing very little cohesion the same form of weight must also be employed, as the first type is apt to go out of sight and be lost. With this system a bed of clay 40 in. thick can easily be traversed, the material being forced out both above and below. For thick beds of clay, however, it does not prove serviceable. As to the cost of the operation, it would appear that for a well varying from 1 to 5 meters in depth, the expense would be 15 francs per yard run, with a mixed filling of rubbish and lime, 20 francs for lime concrete, and 25 francs for cement concrete.

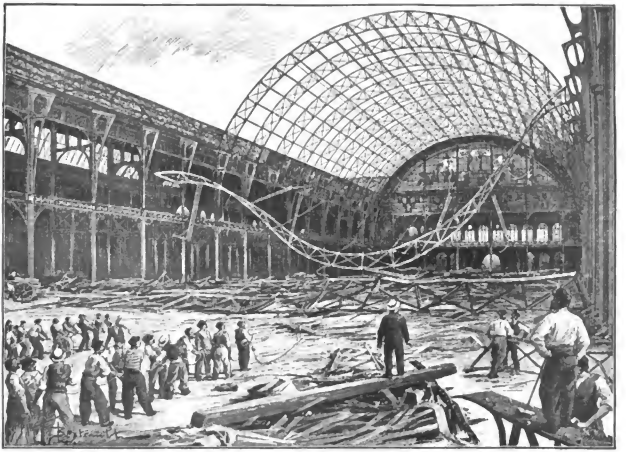
We have said that Mr. Dulac first experimented with this system on his own account, and he was able to

DULAC'S PILING ENGINE.

construct buildings exerting a load of nearly 4 tons per foot upon ground which previously would not carry one-tenth of that amount. He afterward erected a building weighing about 8 tons per square foot upon land where the first fall of the boring rake had thrown up a jet of semiliquid mud to a height of about 30 ft.

The foundations of the new administrative buildings for the exhibition are the latest executed on this plan. There is little else of interest in the structures, which are formed with steel frames, arranged to support slabs of plaster in which are embedded strips of expanded metal or its equivalent; the foundations, however, are of considerable interest, and form one of the many novelties in construction which will be conspicuous at the exhibition of 1900. It may be mentioned that the ultimate strength of the columns is about 20 tons per square foot, and that infiltration of water has been prevented by ramming the holes with broken stone set in hydraulic lime.

For the engraving and the foregoing particulars we are indebted to Engineering, and for our engraving of the demolition of the Palais de l'Industrie we are indebted to L'Illustration. This building is on the south side of the Avenue des Champs Elysées. It was built for the first Paris Exposition in 1855, and the idea was adapted from Sir Joseph Paxton's iron and glass buildings. It forms an immense rectangle, the central building having a handsome elevation surmounted by a colossal group of sculpture, by Regnault. The building, with its long wings, consists of two stories and is adorned with various medallion portraits. The central hall is 51 ft. in height and 632 ft. in length. The building has been used for various scientific and other congresses, and is notable as being the gallery where the famous annual French exhibition called the Salon has been held. The building was so well built that it was removed only with great difficulty.



THE DEMOLITION OF THE PALAIS DE L'INDUSTRIE, PARIS.

[Continued from SUPPLEMENT, No. 1133, page 18115.]

ALFRED MARSHALL MAYER.*

AMONG the acoustic discoveries of Prof. Mayer may be mentioned his observation that the sensation of a sound may be obliterated by the simultaneous action on the ear of another sound of greater volume and lower pitch, but that the converse is not true. The higher pitch, even when intense, cannot obliterate the sensation of another sound of lower pitch. This does not imply that the higher pitch is thus always completely obliterated. Its presence modifies the compound perception after the possibility of singling it out has vanished. The apprehension of this truth caused him to suggest certain changes in the method of conducting orchestral music, but they were not adopted on account of counterbalancing inconveniences in practice.

In 1876 Prof. Mayer discovered that the air pressure on the inner surface of the bottom of a resonator in action exceeds that on the corresponding outer surface. This led to the construction of the "sound mill," composed of pairs of resonators so balanced and pivoted on their supports as to be set into rotation by reaction on sounding near them a tuning fork to which they are adapted. This phenomenon of acoustic repulsion was shortly afterward discovered independently by Dvořák in Austria. Another application of resonators by Prof. Mayer was in the invention of the topophone, an instrument with which the direction of sound at sea, such as that of a fog horn, could be determined with a close approximation to accuracy. His last publication in acoustics was on the production of audible beat tones from two vibrating bodies whose frequencies are so high that the separate tones are inaudible. This paper was read at the Oxford meeting of the British Association in 1894. The existence of such beat tones has been doubted by some. In the present case I was associated with Prof. Mayer during some of his experiments, and had previously had considerable experience in the use of the sources of sound which he employed. As to the reality of the results he claimed there cannot be the least doubt on the part of any person possessing ordinarily acute powers of hearing, who will take the trouble to repeat the experiments.

The study of the physiology of sensation tempts to the investigation of the problems of vision in connection with those of audition. During the winter and spring of 1893 Prof. Mayer became much interested in the phenomena of simultaneous color contrast, of which it may yet be said that no satisfactory explanation is provided by any existing theory of color vision. It has been common to assume that the modification of color perception induced by contrast is due to unconscious motion of the observer's eyes, to error or fluctuation of judgment, or to incipient retinal fatigue. Prof. Mayer devised a variety of methods of presenting these phenomena with unexampled vividness, and on so large a scale as to enable him to arrive at quantitative statements of such subjective color by comparison with standard hues with which they were matched on the revolving color disk. Vivid contrast hues were readily perceptible when the illumination was secured by means of a momentary electric flash, and with entire accordance between different observers who had been purposely misled to expect something different from what they actually perceived. The hypothesis of retinal fatigue, or fluctuation of judgment, or ocular motion, is excluded under such conditions. This psychological element of color contrast led to the development of a disk photometer for measurement of the brightness of colored surfaces. In the use of it a degree of accuracy was attained in excess of that usually found possible with the Bunsen photometer.

While still at the Lehigh University Prof. Mayer began investigations on electricity, on magnetism and on heat, which were resumed from time to time during subsequent years in the intervals between his acoustic researches. His lecture notes on physics were published serially in the Journal of the Franklin Institute, and, subsequently, put into book form. He devised a zero method of comparing the strengths of electromagnets and electrical conductivities, made many observations on magnetic declination, and improved on previously known methods of fixing and photographing magnetic spectra. He undertook an elaborate research on the effect of magnetization in changing the dimensions of iron and steel bars—an effect discovered by Page in 1837, investigated by Joule in 1842 and then neglected for thirty years. It was about this time that an unusually large electromagnet was constructed for the Stevens Institute of Technology, and was employed with much effect in public lectures. One of these, entitled "The Earth a Great Magnet," was given by invitation of the Yale Scientific Club and, subsequently, published. In connection with it a special form of lantern galvanometer was devised for vertical projection, which attracted much notice. Another lecture demonstration which a few years afterward attracted general attention was that of the configurations formed by magnets floating vertically and subjected to the attraction of a superposed magnet.

The multiple or oscillatory character of the electric discharge from a Leyden jar was discovered by Henry in 1842. It was carefully studied afterward by Feddersen, who used a revolving mirror, and yet more fully by Rood, who employed several methods, but more particularly that of the revolving disk with radial slits. Prof. Mayer, in 1874, took advantage of centrifugal action to give steadiness to a disk of blackened paper rotated rapidly between the electrodes employed for transmission of the spark. The perforations were then subjected at leisure to micrometric measurement. Since the rotation of the disk is known, the means is thus afforded for measuring the duration of the discharge and the intervals between the successive sparks which compose it. The conditions were then studied for securing the most nearly simple discharge possible. This served as the necessary antecedent to the successful employment of the induction coil in conjunction with a method previously devised for measuring minute intervals of time with the tuning fork, or rating a tuning fork by comparison with a standard clock. The combination formed an admirable chronoscope for a variety of purposes, but more especially for measuring the velocity of projectiles.

On the general subject of heat Prof. Mayer published several articles. The first of these, in relation to waterfalls, has been already mentioned. In 1872 he devised a method of tracing the progress and determining the boundary of a wave of conducted heat by taking advantage of the variation in color with change of temperature which is characteristic of certain double iodides. The same method was applied three years afterward to the securing of thermographs of the isothermal lines of the solar disk. In 1890 he gave publication to a paper on the determination of the coefficient of cubic expansion of a solid from the observation of the temperature at which water in a vessel made of this solid has the same apparent volume as it has at 0° C., and on the coefficient of cubic expansion of a substance determined by means of a hydrometer made of it. The method was applied to several different substances, including brass and vulcanite. This led to a general investigation of the properties of vulcanite, which was published soon afterward. One of these properties is its remarkably large coefficient of expansion, exceeding that of mercury.

Soon after the publication of Roentgen's discovery of a new species of radiation Prof. Mayer's interest in this was aroused, and in June, 1896, he published the outcome of his investigation of herapathite, which had been employed by him to test the possibility of polarizing the Roentgen rays. Formulæ were deduced for the transmissive powers of several substances for these rays,

* By Prof. W. Le Conte Stevens, in Science.

including tourmaline, herapathite, glass, aluminum and platinum.

Prof. Mayer's last scientific work was an experimental investigation of the equilibrium of the forces acting in the flotation of disks and rings of metal, and an application of such rings to the determination of the measure of surface tension of liquids. The method was wholly new, and the agreement among results was remarkable. At best, it has been difficult in the past to secure reliable results in work of this kind, and the present work is fully equal, if not superior, to the best hitherto accomplished by Plateau and Quincke. It was done during the intervals between periods of acute physical suffering, and its appearance in the American Journal of Science for April of the present year preceded by only a few days the paralytic stroke which demonstrated that the investigator's life work was already ended.

In this brief sketch of Prof. Mayer's labors but little has been said of his numerous happy devices for lecture demonstration. His restless ingenuity was ever ready for any demand, and his mechanical aptitude was so directed by a delicate æsthetic sense that he could never be satisfied with any objective proof which was not neat and simple, as well as adequate. A few of these he published from time to time. Among them may be mentioned methods of measuring the angle of inclination of the mirrors employed in Fresnel's interference experiments; of obtaining a permanent trace of the oscillation plane of the Foucault pendulum; of registering and exhibiting the vibration of rods; of deducing the fundamental laws of electric repulsion by means of the pendulum; of measuring potentials and specific inductive capacities with the spring balance electrometer; of proving Ohm's law, and of expressing electric potential as work. Many of his demonstrations in acoustics were gathered into a small volume on "Sound," and have thence been copied into the elementary text books of to-day. The same may be said of a little volume on "Light" prepared with the co-operation of Mr. Charles Barnard. In the student laboratory he was as efficient as in the lecture room, fertile in devices and ever insistent upon a high standard of accuracy. No one knew better than he that demonstration and practice work are of insignificant value in comparison with investigation; but he kept always in mind the fact that, in America at least, the physical investigator is nearly always compelled to be in some way a teacher, and that in teaching physical science demonstration and theoretic instruction must go hand in hand. He was conscious of his skill and, naturally, took keen pleasure in exercising it successfully. That in so doing he gave pleasure and help to others is manifested by the extent to which his methods have served as models.

The manipulative skill and tactile delicacy which are so necessary as adjuncts to independence and ingenuity in the laboratory were applied with no less success by Prof. Mayer in outdoor recreation. Early in life he became an accomplished marksman; and during manhood, as long as good health lasted, he was an ardent and exceptionally successful sportsman. His field and laboratory interests were combined in his application of the tuning fork to the problems of gunnery. In the Century Magazine he published a number of articles on sporting subjects. These were incorporated, along with contributions from other sources, in a volume entitled "Sport with Rod and Gun in American Woods and Waters." This volume was edited by Prof. Mayer, and for it he specially prepared two valuable articles, one on "The Shot Gun" and another on "The Blow Gun."

In addition to these literary labors, Prof. Mayer contributed many articles to the cyclopedias of Appleton and Johnson, besides occasional popular articles on scientific subjects for other media of publication. In acknowledgment of his earlier contributions to science the degree of doctor of philosophy was accorded him in 1866 by Pennsylvania College. He was admitted to membership in the National Academy of Sciences in 1872, and was a member of each of the leading scientific societies of America, besides being a corresponding member of the British Association. He served during one year, 1873, as an associate editor of the American Journal of Science, and during the first eight months of that year five articles from his pen appeared in its pages. The partial failure of his eyesight then necessitated cessation from all work, and a considerable part of the next scholastic year was spent in England, where his reputation had preceded him and where hospitable entertainment was accorded by the most prominent representatives of science.

In the closer circle of personal friendship it is hard to speak with impartiality while the sense of bereavement is still fresh. A man's personality penetrates into all that he does, into his writings quite as unmistakably, if less positively, than into his conversation and the atmosphere of his home. In a eulogy on Joseph Henry, to which I listened at Cambridge just seventeen years ago, Prof. Mayer said: "His best eulogy is an account of his discoveries; for a man of science, as such, lives in what he has done, and not in what he has said, nor will he be remembered for what he has proposed to do." In comparing Henry with Faraday he remarked: "Each loved science more than money, and his Creator more than either." Mayer proved himself a worthy pupil of Henry, and their friendship grew in strength until broken by the last great Destroyer. His words may now be properly applied to himself. The characteristics of the gentleman, the high toned man of honor, were born in him. They needed no cultivation beyond the natural development and confirmation which accompany the attainment of maturity. Those who were favored with his friendship need no reminder of his generosity, his ready sympathy, his quick insight and hearty appreciation, his enthusiasm verging sometimes almost upon that of boyhood.

The value of Mayer's work will be tested by time. For some parts of it he will unquestionably be long referred to as an authority by stranger as well as friend. He dwelt in an atmosphere essentially unfavorable to the spirit which directed his work, for nowhere in the world can there be found so high a degree of general civilization conjoined with so small a degree of general appreciation of pure science as in America. This may be said with full recognition of the abundant rewards here accorded to science successfully applied in industrial fields, and of the rich endowments given by wealthy individuals to some of our educational institutions. But the man who advances theoretical science in America receives not a tithe of the recognition given to the inventor who puts on the market a merchantable device which pleases the multitude. Prof. Mayer would have done his scientific work to better advantage in France and Germany. But be this as it may, we who knew him in his work must now know him only in memory. To have had him as a co-worker and friend is now a sad pleasure, and one that nothing can take away.

IMPROVIDENT CIVILIZATION.*

A PLEA FOR THE APPLICATION OF SCIENTIFIC METHODS TO THE AMELIORATION OF SOCIO-ECONOMIC DEFECTS AND DISORDERS.

By Richard T. Colburn.

II. DECADENCE OF RACES.

The abstraction of numbers by warfare and the privations of army life, vast as they were, do not account for the decline and degradation of the great empires of the past. Besides, decay seems to overtake the conquering as well as the conquered race; and there are instances where the enslaved have become in turn enslavers. Mere numbers are not strength nor tenacity of nations: witness the Hindoos. The old Greeks were not numerous, but what they lacked in numbers they made up in vigor and sagacity.

What are these other causes of premature decay? In other words, is there a natural term of life for races, as for individuals—a cycle of growth, maturity and senility? Dr. Charles Pearson, in his work on the "Life and Character of Nations," has attempted to answer these questions and, in addition to other minor causes, traces the decline to an inherent difference of stamina or staying power in the ethnic divisions of mankind, corresponding to our present external classification of races by color of skin and hair. The startling conclusion he reaches is that the swarthy or dark-skinned races are destined to outlast, and of course supplant, the lighter-skinned or Aryan group. The evidence is scanty and inconclusive; but it is significant and carries us back directly to the interesting controversy now waging between Prof. Weismann and his critics as to the quality of the germ plasma and its transmission without impairment or improvement, into which we cannot here enter. The rival hypotheses of Galton and Cope deal, however, with problems belonging to the sociologist as well as the zoologist and microscopist.

The doom of the light-skinned races, according to Pearson, is fixed, for it is not to be averted even by admixture. The bearing of purity of race on its persistency is far from being worked out. So far it goes to show the active dominant types are mixed; while the purer races are few, isolated and nearly stationary in civilization. Whether these differences be due to reversion of ancestral types—atavism—or to the greater complexity of organization and nerve strain, is an interesting study which we must ask the biologist and somatologist to elucidate for us.

Just why the builders of Assyrian, Phenician, Nile Valley, Yucatan, Grecian temples, thousands of years ago, have not left their qualities to their descendants, may be due to other causes than the stability of the somatic cell or to intermarriage; for instance, denudation of forests, inroads of infectious or contagious disease, insect pests, errors in diet, the warrior occupation, or a combination of all in greater or lesser degree. The higher types of men seem to have arisen along the broken coast line, or in the moderately elevated regions. The great plains or steppes have not been favorable to density or quality of population or to courage or vitality. The liability to periodical prairie grass or forest fires may have stunted the development of men and animals alike. Meteorological conditions are important to flora and fauna; the annual mean of sunshine, the precipitation of moisture, the range of extreme temperature, and the degree of humidity are factors of survival in the geography of races. The more northerly seem to prevail over those nearer the equator—provided we do not go too far north—due allowance being made for the modifying influence of ocean currents and altitude above sea level, the lines being not exactly isothermal but hygrometric. Singularly enough, there are notable exceptions to this rule. In the dry deserts of Arabia are to be found, among a population of Bedouins, chiefs of noble mien and splendid form, descended apparently without dilution from a remote ancestry. So in Abyssinia, almost a hermit nation, as Slatin Bey tells us, the natives combine great physical endurance and courage, under the most adverse surroundings of plant life and notwithstanding the general prevalence of syphilis, long supposed to be an escutcheon of civilized mixed races, and a very sword of destruction. The example of the Jews so frequently cited in favor of purity of race is important evidence, but complicated with other than ethnic factors, such as the Levitical code of hygiene, the rite of circumcision, the confraternity caused by ostracism, restricted occupations and social temptations, each of which plays a part in the endurance of races.

As a matter of fact, the population of those nations which make enumerations has largely increased since 1815; but this has been made possible by the opening of new sources of food supplies, for which exchanges of manufactures have been given. In spite of the migration of more than twenty millions to distant parts of the world (America chiefly), every considerable area has increased its own numbers; and it is only quite recently that France, the sole territory where emigration is practically nil, or less than the immigration, is found to be stationary or slightly declining. There is a well founded suspicion that what is now happening to France will, in due time, happen to the others from the same causes. Is the fate of Rome, Carthage, Venice, Thebes, to be repeated? Macaulay's New Zealander sketching the ruins of London Bridge is prophecy alluring to the historian, but it also finds ready acceptance among social philosophy essayists, who offer, however, the most divergent array† of moving causes, such as the decline of marriage, vaccination, flesh eating, narcotics, condiments, degeneracy, iced drinks, sewerage, irreligion, destruction of caste distinctions, etc.

Unless we assume that there is in each new birth a redemptive power, a dropping of the taints of parentage, the human race ought logically to have come to an end long ago. In some way, as yet obscure to us, in which natural selection plays its part, health must be catching as well as disease; otherwise the major and minor pestilences would have brought a quietus. Phthisis is a comparatively modern disorder. Cancer is another of the internal lesions coming to be known as induced diseases of the blood which may be carried about to all climes and propagated with fatal facility. Whether the special bacillus starts the decay of the lung tissues or follows as a sequence of the decay seems to be still in doubt. Pathologists are just now enamored of the theory of antitoxine inoculation—a sort of tame medical ferret sent in to combat the invading rodent organism. If this is our best hope, the ravages of tuberculous, cancerous and febrile ailments leave civilized races but a short respite.

The researches of Sternberg and Metchnikoff into the function of the leucocytes as guardians of the normal state of arterial currents is more intelligible and logical—if the hypothesis of phagocytosis shall be established—as this leaves the work of eradication of the blood deterioration in the hands of the organism itself, not wholly beyond human control, makes it largely an affair of metabolism of food into living cells with a counterpart activity of the emunctories. The function of the ductless glands in the formation of these blood cells is the corner of histology and pathology now awaiting special researches, and from which we may expect refreshing relief from the antiquated fetish theory of antagonizing drugs.

History concurs with physiology and with statistics in the view that civilization is not favorable to marriage and fecundity, though it may be more propitious for the rearing of offspring. In spite of the surcharge of sex passion which nature has thrust upon men, and the equally enticing wiles and coquetry of women, most of whom must look to marriage as a career, it is more and more of a failure. Polyandry and polygamy are being crowded out by monogamy, but the philosopher is tempted to ask whether monogamic union and the family as we know them are also to disappear; and, if so, what will take their place? Shall it be a return to celibate asceticism or a resort to the state as foster mother?

For some occult reason it is not as easy to be born into the world, now and here, under civilized conditions, as formerly under semi-civilized. The proportion of stillborn may be less in our days than formerly; it probably is, but the infant mortality is greater. The mortality of parturition increases alarmingly, notwithstanding aseptic devices. One may well ask why the parturition of the homo sapiens is attended with so much hazard. Whether the civilized man habitually mates at a later period in life than the savage, after the pelvic bones and ligaments have lost much of their elasticity, or that a larger cerebral development of the modern infant, out of proportion to the bony or muscular framework, renders him less viable; or whether the replacement of the earlier sage femme by an accoucheur with his case of instruments and anesthetics is more responsible for the increased mortality we leave to gynecologists to decide. The change of both sexes to indoor employment in shops and factories rather than arduous labors out doors accounts for some of the loss. The net result in grandchildren may be the same as for prehistoric man by reason of better care during the period of adolescence.

If our census statistics are trustworthy, prudential as well as physiological causes are at work in the same direction. Families do not arrive so early, nor in such quantity, as in primitive life. The perpetuity of the race is left to the unthinking classes. The aversion to child-bearing crops out (especially in large cities) in various ways. The practice of abortion, very common in Asiatic countries, and suspected to be very prevalent in Europe and America, proceeds, of course, from prudential or economic considerations, fashion, or avoidance of social penalties. We know that the advent of girl children to the Chinese and some other peoples is looked upon as misfortune; as might be expected, feticide and infanticide are common. Fear of want, love of pleasures and varieties, dread of pain and risk of death, the handicap in matter of house renting, awe of the religious authority—all play their part in this great matter of diminishing population, which has engaged the attention of the French savans and legislators, and the sacerdotal government of Quebec.*

The optimist queries: "Why worry about the extinction of the human race?" which reminds one of the American Plato's reply when told by an Adventist that the end of the world was at hand, viz., that "he could get along very well without it." The question whether perpetuity of race is desirable is equivalent to asking whether anything human is worth preserving. It is answered by science and ethics alike: whatever may be the rights of the individual over his own life, the plain inference from study of nature is that parents exist more for the sake of children than children for parents; life is essentially a sacrifice of the passing for the coming link. The more serious query for us is to know how it may be lengthened, or extinction avoided. Not one of us cares to be of a declining or prematurely dying race.†

* An address before the Section of Social and Economic Science of the American Association for the Advancement of Science, August, 1897. Mr. Colburn is vice-president and chairman of this section.

† Mr. H. A. Reed, for instance, finds in the proneness to alcohol and narcotics an artificial or[illegible] exterminating those least able to carry their load of poison.

It was reserved for Mr. Brooks Adams to discover that the scarcity of the circulating medium (in this case the depreciation of white metal is in mind) was decimating the white race.

* The birth rate of the New England States ranges it seems between 18 and 22½ per mille, while that of the far West States is still less, or less than that of France, and, being lower than the death rate, means, unless redressed, ultimate extinction.

† On this very point an interesting and instructive bit of testimony has recently come to hand.

The opportunity of studying the aboriginal life of those interesting islanders in the Pacific Ocean is passing before our anthropologists, and physiologists have extracted the whole lesson for the benefit of learning. The British government recently appointed a commission to examine into the decline of the population of the Feejee Islands. The proceedings, in [illegible] amusing, might have been more instructive had it been composed in part of trained feminine obstetricians. The inquiry disclosed a birth rate surprisingly high, much higher than the average of Europe, and a death rate still higher, and all sorts of reasons were offered to account for it, as it was a concomitant of the coming of the Caucasian race, the onus fell on traders and missionaries. The testimony of an elderly accoucheur, familiar with both conditions, revealed the fact that the native women had become indifferent to the obliteration of their own people, and this because the [illegible] and [illegible] had been taken out of their lives; a sense of sin had been introduced, and these Gardens of the Hesperides had

Gratification of the gustatory nerves, located at the back of the tongue (which is not at all identical with the appeasing of hunger), together with the convivial propensity of man, a corollary of his gregariousness, is responsible for a part of his shortened longevity. It has its double aspect of physiological and psychical influence. No people suspect their daily food, or beverage, to be harmful; for the most part they would as soon tolerate criticism of their religion, their patriotism, their wives, as their bill of fare, but each in turn freely expresses his contempt for the table of the others. Is there not some underlying vice in the habitual food of the civilized world, which, of course, includes its preparation? Of the grass seeds which furnish the staple for the bulk of the world, rice constitutes at least half. Christendom prefers the wheat, rye or maize, which we esteem as the superior grain; yet the Chinese and Japanese contrive somehow to nourish stout sinews, though more diminutive bones, and acute brains and courageous hearts out of the blander grain without recourse to much animal food. Their superior recuperative power in hospital against injuries and lesions of disease is notable. The conquering quality of British tribes is believed to be due to the ample ration of beef, of the German to his of beer and sausage; of the Mediterranean littoral, to their free use of wine. To modern science we are indebted for the explanation that the decoction of the coffee berry by the Levantines and of the tea leaf by the Mongols for ages has probably contributed to their survival, by supplying a boiled or fermented liquid, which was doubtless comparatively more free from morbific bacterial organisms than the polluted wells from which the water was drawn, in those densely crowded and ancient abodes. The medical view that life is shortened more by overeating than by starvation, in its ordinary sense, is confirmed by the chemist's laboratory tests, and by the spectacle of contrasted races. Can we not, while imparting our science, philosophy and literature to the Chinese and Japanese, take a lesson or two from them on diet, and perhaps on clothing and house furnishing also? Their comparative exemption from phthisis, cancer, insanity and neurasthenia (aptly described respectively as atrophy, mutiny, and exhaustion of the cells) alone should put us upon our inquiry.

A leading American physician has said, more or less jocosely, that compared with the present, the coming man will be a big headed, small bodied, puny limbed, bald, toothless, spectacled and toeless creature subsisting on concentrated foods, to which we may add the qualifying remark that he will not keep coming for any long period. The fate of that people where teeth and eyes decay and dentistry and opticians flourish is not at all conjectural. It concerns the student of physiology and sociology alike to ascertain what causes are at work impairing the digestive organs, the teeth and eyes of civilized peoples, and in what respects the as yet uncivilized have a manifest advantage.

Making due allowance for the power of accommodation of the system whereby blood and tissues are made out of so wide a range of food stuffs, the conviction forces itself upon us, seeing the effect of alimentation upon plants and animals, that while the norm may be a shifting one from youth to age, there is a norm, and that deviations from it must tell upon the vigor and endurance of the race. The very general use of salted and smoked meats for example; has not that had much to do with the increase of gouty and rheumatic affections, usually attributed to acid fruits or wines? This practice could easily be dispensed with, by the use of cold storage and desiccation.

Then again, the civilized man, and especially the woman half of him, habitually lives in a warmer, closer atmosphere than the savage. Have not our airtight houses, with their stoves, steam pipes, furnaces and weather strips, contributed not a little to diseases of the respiratory organs? Nay, the presence of a cellar under the dwelling rooms is a suspicious coadjutor. Then there are the germ dust gathering carpets, curtains, portieres, plush furniture—are they not in some degree responsible for the spread of pathogenic bacteria upon tissues already weakened by defective nutrition?

An English physician, lecturing to a recent graduating class, as reported in the Lancet, ironically said, by way of caution against excess of confidence, that "the average life of a fact in physiology is about four years." Intended as a reproach upon the practicing medico for his running after new therapeutic discoveries, it is also an encouragement and a compliment that one error can be run down, and superseded it may be, by another, in so short a space as four years. Alas! it takes a much longer period, on the average, to exterminate some of the so-called facts of social and political science.

III. PERNICIOUS COMPETITION.

Prof. Cairnes happily hit off one of the most salient features of the literature of political economy, of the passing generation at least, when he styled it "a more or less handsome apology for the present state of things." One cannot but feel that it has been for the most part a thrashing over of old straw, and even now with enormous output of printed matter, there is very little beyond a rehash of the old controversies about wages, funds, rent, balance of trade, incidence of taxation and so on. Writers divide themselves into three classes, each of them defective without the other two; the historians and academicians who have gone over the writings of their predecessors and who know but little of the business of the world; the statisticians who put faith in their ability to reckon up into tabular form that which is incomputable, as well as that which is, and whose industry is out of all proportion to its value for scientific use; then there are the enthusiasts who [illegible] profoundly dissatisfied with the present distribution [illegible] wealth or the conditions of industry, and who [illegible] schemes of reform and then turn the [illegible] figures round as upon a swivel in support of the ideas. Doctrinaires, who for the most part write the treatises and books about finance and trade, know but little of the world about them; while the bankers, arbitrageurs and movers of the world's crops and tonnage are too busy to write about what they understand. The result is the literature of political economy is about one generation behind the practice. Especially is this true of international finance.

The new world, having a virgin territory to occupy and improve, has run in debt to the old somewhat recklessly. The burden of interest and repayment of the capital is irksome. Extension of the debt at low rates is dependent on capacity to pay if demanded. So long as we are handicapped with this mountain of debt, it is in the power of a few foreign holders of our promises or titles to property to bring on a panicky feeling at any time they choose, though fortunately it is not for their interest to do so, but the time may come when it will be. Besides this hampering of debt, there has been an unconscious extravagance, of which we shall have more to say when we speak of the tendency of luxury. In a wholesale way we have been exchanging our liens on and evidences of ownership of lands, timber, railroads, manufactories, mines, breweries and the like for shiploads of merchandise, the bulk of which we should have been the better for not having at all, and nearly all of which we might have made for ourselves. To get square will cost us hard work and self-denial. With the exception of this broad distinction of debtor and creditor nations, and of the latter supplying articles in which there is limited competition, all the world is engaged in a general scramble in which cheapness of production is the goal. The industry of nations has developed into a species of hostile contest, not quite so hazardous as actual warfare, but demoralizing and exhausting in a less degree only. It is as if all marches were required to be forced marches; and all business must be conducted on the brink of the precipice of bankruptcy. It was always so within the confines of a given territory; but the substitution of steam for animal power and of dexterous machinery for handicraft has not only intensified the competition within the old boundaries, but has also set the maritime nations to trying to undersell each other. In this contest for cheapness, standards of living, hours of labor, habits of frugality, depth of purse, vigor of body and acuteness of mind all have their part to play, and the efficiency and economy of government, stability of institutions, probity of character are also pitted against each other. Individually and collectively, an ordeal, growing more and more severe, confronts all trade, agriculture and manufactures. When the five hundred millions of Eastern Asia shall have grasped our mechanical inventions, it is idle to suppose the occidental standard of living can be maintained if the régime of unrestrained competition is to continue.

This is the crux of the labor problem, and also in large part of the commercial and financial problem. To the older writers aiming their arguments against the arbitrary and often absurd restraints of trade by statute, it seemed as if perfect freedom of trade was an ideal state of things, to usher in a millennium. The question has become too broad for local statutes. Freedom of trade breeds extravagance, improvidence, overproduction, followed by panic, depression, enforced idleness, discontent, and so on in recurring cycles. The struggle is too keen; it is the cosmic struggle for existence intensified, socially wasteful and destructive. Too many men are in trade; too many trying to "live on their wits," with the result that the peasantry of all nations are being worked too hard and robbed of their share of the gross product.

Less than half the population of Christendom is at work, half of those in agriculture, fifteen per cent. in professions and public service, while ten per cent. are in trade and transportation. Left to itself, we may be sure that by natural selection the weaker in trade will be forced to the wall and the few fittest will survive, but the competition will not stop; that must go on unless some general corrective is discovered. The tendency in domestic trade may be found in the mammoth department stores, which are surely crowding out their smaller competitors, and this results in such dislocation of trade from its usual channels as to engage the attention of legislatures and turn elections. It is obviously the fact that in nearly every city or town there are about five times as many merchants in a given line of business as are necessary, each with its corps of clerks, bookkeepers, delivery wagons, etc. If the saving of a concentration is shared with the customers, as it certainly is in practice, the community of buyers will have no reason to complain, but it is otherwise with the producers and manufacturers, who must submit to the prices dictated by the big concerns, who are frequently able to take the whole product or refuse any. The power of concentrated capital and marshaling of labor, which has been going on in mechanical occupations, has now spread into trade, shipping, finance and even into educational pursuits.

The smaller rivals are seeking shelter with the larger ones by absorption or alliance to escape a worse fate, as we noted in the case of political aggregations. This has led to consolidations and leagues under the name of trusts or other fiduciary contrivances. Railroads cannot escape from being dragged into this pernicious rivalry; they are under control of their patrons rather than of their stockholders. The legislatures, sustained by the highest courts, say they shall not combine "in restraint of trade;" though they are reluctant to cut each other's throats in competition, they are compelled to keep in the game at the same rapid pace as their customers. Regimentation and coercion in labor, hardly less intolerable than regimentation and obedience in militarism, are threatened unless some remedy can be devised. Laissez faire points toward a cruel and despotic struggle which is discouraging in the extreme; nor is there in the province of legislation apparently any adequate relief.

The step from a status of slavery to that of serfdom with a claim on the land for subsistence was important; the evolution from that to voluntary contract was equally so, and no people holding to either of the former systems of labor can hope to contend against the latter. But the régime of free contract is hardly a finality. The rankest injustice is perpetrated under its forms all over the world where proprietary rights are acknowledged. It is, of course, far better to require the consent of laborer and employer, but with this consent great wrongs are possible—are, indeed, common. This is a very grave question in social science, "how to put a curb on astuteness," as a magazine writer has styled it; how to shield the weaklings and credulous from spoliation by the crafty and unscrupulous. How shall the ignorant and confiding part of the population be safeguarded against overreaching, temptations, wiles and wares set for them and for each other without opening the door to still greater evils? These lures are of all sorts and degrees, from the knave who offers to sell counterfeit money or lotion to beautify the complexion to the banks, insurance and trust companies of many kinds; nor are the learned professions above setting traps for the unwary or of suborning the press into becoming accessories. Look at the enormous outlays for advertising proprietary medicines, which debauch and befog the public conscience, if they do not injure the public health.*

It is not easy to suggest a rectification of the evils of unbridled competition, especially where statutory restraint is either aggravative or impotent. With some hesitation I venture to point out some of the underlying causes of our trouble.

First, let me ask, "Why do men engage in and remain in trade, or enter upon any of the professions?" The usual answer is, "To earn a livelihood;" but this is not all. In civilization certainly there is the further motive of a desire to succeed, to become a master in the craft if possible, and whether or no, to amass some surplus of possessions as a provision for old age, to win society prizes, to dower daughters, start sons in business, perhaps found a house, endow a charity, build a monument, or leave a fortune, all of which motives are of the mind. We each of us see, or think we see, the wisdom or necessity for any one or more of these aims and purposes in life. Men and women are the slaves of ideas, and words stamp ideas so firmly on the average mind that they are with difficulty dislodged. What different ideas are conveyed by the words "success in life"! Not one in a thousand analyzes the thought to see its relativity or instability. If there were no need for a provision for old age, or for charity bequests, the extra industry would be needless too. If there were not the ambition to win, to excel, to outrun or outgather, the tremendous exertion of the rivalry would be stupid. Partial attempts are made to do away with the necessity for individual provision for the infirmities of old age by providing retiring pensions for the army, and in some countries for civil officers also. For those not directly in the service of the state, poorhouses (which are too often poor homes) are established by law; and some states now propose to aid by labor pensions also. These arrangements are the just and necessary sequel of a state of things where human life and vigor are sacrificed wholesale in the strife for cheap production.†

Second.—The eradication of the vanity of emulation, the desire for distinction, may be more difficult, but something might be effected in that direction. Suppose, for the occasion, that there were no prizes to run for, there would be less racing; I mean not material trophies, but the distinctions and adulations of winning in any contest, athletic, professional or social. If, by some happy contrivance, as much pains were taken to encourage confraternity and equality of estimation as is now taken to encourage leadership, and dissimilarity of estimation, would not much of the social strife and worry disappear? Within the family such inequalities are generally frowned upon. Can we not extend the ethics of the family beyond its pale to the whole social organism? The idolizing tendency of human nature is one not to be proud of or stimulated, but rather to be repressed. Why would it not be well to commence with infancy, in school or business, and abolish all prizes, honors and bribes of every sort for simple good conduct, or for doing one's best? Where there are winners there must also be losers; and for the latter there is very little regard outside the family, which discouragement is of itself conducive to further failure, bitterness, malice or suicide. The office should seek the man rather than go to the persistent intriguer or shameless "hustler." Aside from the fostering of an unwholesome sense of superiority, does not the whole practice of merit marks and competitive examinations of our schools and colleges work badly, in favor of a certain superficial readiness of mind which will have advantage enough over a less precocious maturity without conventional badges? The honors and emoluments of public and private station go together, a duplication of pay. It is one of the most somber traits of the older civilizations surviving in great vigor, the

[illegible] ... and disciplinary plantations, workshops and ... of a ... [illegible] ... the Hawaiian group; the ... is fatal not only to the life of the inferior race, ... the worry of competition, and modern ...

[illegible] ... with our competitive civilization and ... itself, and in Buddhist lands? Have they ... that would be full enough of ... [illegible] ... of the Japanese babies as compared with ... [illegible]

* H. J. Davenport, in his recently published "Outlines of Economic Theory," tersely sums up the evils of competition in trade:

"The stimulus of private interest works out in a vast amount of crime and disorder which necessitates, in policemen, courts, juries, sheriffs and lawyers, the expenditure of social energies. Likewise in purely private affairs the expense of preventive methods against ill faith and dishonesty is a weighty matter. Outlays of this sort would be relatively small in the collectivist system. There are large wastes of energy in competitive attempts to give to cheapness the outside gloss of value. Shoddy in cloth, paper insoles in shoes, clay in soap, sand in sugar, not only waste the energy of putting them in, but largely destroy the usefulness of the honest product. Socially speaking, all this cheapness is excessively dear.

"There is a similar compound of waste in the enormous outlay for newspaper puffing and lying. The entire system, also, of marketing through agents and commercial travelers has in it large elements of waste. The excessive multiplication of middlemen generally falls under the same head.

"The present system is also responsible for hordes of human beings living by their wits or their worthlessness: social make-weights, paupers, vagabonds, speculators of useless types, prostitutes. Parallel with these are the respectable do-nothings, the leisure rich, the inheritors of wealth, the coupon cutters. Within this class of respectable make-nothings must be reckoned also the table and waiting maids, the outriders, footmen, servants and flunkies whose energies never work out in any utility, for which the world has any real need. And in a background of misery stand the unemployed, with whom, as misery, we are not at present concerned, but only as waste. Never an inconsiderable class, they swell in times of depression to an enormous army."

"Fashion demoralizes industry and fosters starvation. Warehouses are filled with commodities to supply a demand that has vanished or to forestall a demand which never appears. Beggary and ruin result. A novelty strikes the popular fancy; there follow extensive profits, intense production, multiplied factories, prosperous allied industries, growing cities, in flocking laborers, investment, speculation. Fashion grows cold when the commodity becomes cheap and [illegible]; then failures, closed factories, [illegible] capital, collapsed boom, [illegible], hunger and riot. Almost all industrial centers know something of this experience. All over the world there are Nottinghams regretting a banished lace industry. The law of industrial peace is ebb and flow, change and uncertainty. Fashion in commodities is parent to business gambling, great fortunes, great losses, feverish activity, feverish lassitude, fluctuation and bankruptcy." (Pp. [illegible] et seq.)

† Mr. Plimsoll convinced his government that near 2,000 sailors' lives were recklessly lost yearly through overloading. We may note in passing that the need of such provision is seldom found among proprietors of the soil, small or large; the farm is the savings bank and, in the hands of a practical farmer, a very good one. Seldom is the working farmer often spurred by the ambition of vanity "to cut a figure" or win some distinction in the [illegible] ranks. If himself or family lacks a pension at the outset, it is [illegible] a sort of contribution to the common enjoyment, and not as a distinction of social caste, nor does he require the relief of pauper acts in old age.

readiness to fall into line obediently behind the nominal leader. When physical prowess was the surest road to distinction, the sway of one man power was a necessity. In these days of deliberative assemblies of quasi-equals it is a vestige of former subservience. Perfect equality of mind, or stature, we shall not have; but there is no justification for putting the tall man on stilts and lopping off the shorter ones. This is just what our present civilization is blamable for doing. The winner, if only by a nose length, or by a scratch, is elevated out of all proportion to his excellence. If we must "play pretend" at all, why not minimize the differences between coadjutors, rather than exaggerate them? Some may declare that, all men not being alike, they cannot be treated alike. Certainly not, but we ought not to magnify or multiply the rewards for the superiority which, if it does exist, nature is sufficiently discriminative without the help of social man.

Third.—Corollary to the provision for maintenance in old age or disability is the necessity for some system of more constant and steady employment prior to decrepitude. At the best of times fully ten per cent. of able-bodied laborers, mechanical or factory hands, are living in enforced idleness, and in times of depression the percentage is very much higher. The difficulty here, too, is in part psychical. It is not enough that the laborer wanting work and the employer wanting work done succeed in finding each other; the latter must be satisfied not only as to the wage he can pay out, but also as to the character of the proposing laborer; he does not want to introduce discontent or disorder among his men. This trust or confidence is almost impossible in an idle population drifting across a continent. Without going so far as to affirm the right of the willing laborer, even if he have a family depending on his exertions, to employment by the state; still the community has him and his family to support in some way; why not do so in a systematic and economical way? It may be said that it would discourage saving habits, but the present plan does worse; it begets a lack of sympathy. If every county in each State (it would operate badly to have it in some and not in others adjacent) were to lay out in advance some useful public work, sufficient to employ the quota of discharged laborers, at a bare living wage, to prevent tumult and pillage, credit being resorted to if necessary, the positive benefits might not be so great, but the unseen damage might be averted. Central Park, in New York City, owes its existence to an impromptu politic stratagem of this sort; and there is not a city or county that might not resort to similar works of transport, embellishment or sanitary aids, greatly to its advantage, and thus mitigate the severity of panic waves.

(To be continued.)

DENDROBIUM VICTORIA REGINA, LOHER.

OUR illustration gives a representation of this pretty species. The plants were sent to Messrs. Protheroe & Morris, who offered them on Friday, June 18; and, therefore, the proof of the correctness of the description, which purchasers look so anxiously for in the matter of a "blue orchid," was not long delayed, for specimens of it have flowered in several collections and have generally been considered satisfactory. The specimens vary somewhat, but all bear white flowers colored on the outer halves of the segments with shades of blue. It is stated to be a native of the Philippines, growing at an altitude of 6,000 feet. The plant from which our illustration was taken was exhibited by Thomas Statter, Esq., Stand Hall, Whitefield, Manchester (gr., Mr. R. Johnson), at the meeting of the Royal Horticultural Society on August 10, when it was given an award of merit.—The Gardeners' Chronicle.

AGRICULTURAL.

ALL the counties of the State of Ohio are now organized with from one to six farmers' institutes in each county, and from reports of the meetings of these institutes, from November 30, 1896, to February 27, 1897, as made to the Ohio State Board of Agriculture, the board publishes an interesting volume of lectures and papers thought to be of value to farmers, stock breeders and horticulturists, from which we make a few extracts. It may be interesting to note that the attendance at these institute meetings varied from about 200 to 800, presumably mostly farmers, at each meeting, the total attendance at the series being given as 85,469.

CONDITIONS OF PLANT GROWTH.

By S. H. HURST, Chillicothe, O.

Next to fertility and water in the soil, mellowness or refinement is a factor in the growth of crops, and this condition of the soil is almost wholly under the control of the farmer. Barnyard manure or decomposed vegetable matter of any kind is promotive of mellowness, and a degree of moisture is necessary for the most inviting plant bed. But refinement by cultivation is generally an absolute necessity. Years ago it was common to see corn planted or wheat sown in cloddy ground where a half crop seemed an impossibility. But improved methods have brought the clod crusher, the smoothing harrow, the disk harrow and drag into general use, and now no intelligent farmer thinks of planting or drilling for any crop until his soil is in good condition. A good seed bed is the first consideration. We refine and mellow the ground before planting, to prepare a mellow seed bed, and we cultivate and refine the soil as the plant develops to maintain a mellow root bed. In the work of cultivation it is no error to say or to suppose that we cultivate the crops. We do not, primarily. We cultivate the soil to make it mellow and fine, so that it will hold the fertilized moisture, and thus invite and promote root growth and root feeding. We certainly do not want to cultivate a plant simply to lacerate or destroy or shorten its roots, thus depriving it of the power to feed on the vegetable nutrition or fertility around it, and with our modern ideas of level culture we do not plow to "hill up" the plants. The two legitimate offices of cultivation in crop growing are the refinement and mellowing of the soil and the destruction of the weeds. After corn or potatoes are planted, it can scarcely be desirable to plow at all to any depth, if the soil between the two rows is quite mellow, so that the roots and rootlets can push out in every direction, and drink in the fertile water. But if, after planting, the ground is "packed" by heavy rains, it will doubtless be well to plow once with a set of long narrow shovels to mellow up the land again, lest in its compacted condition, dried and "baked," as we say, it would be almost impervious to root growth. But if the middle is continuously mellow, then only the surface should be stirred to a depth of one to two inches, and this by a fine short-toothed harrow or by a sharp fluke harrow, or by a system of sharp steel knives, which, attached to a harrow frame, cut off every starting weed just below the surface of the ground. This shallow cultivation of the ground destroys all the weeds and makes a sort of mellow mulch which lies like a blanket on top of the ground, breaking up the capillary power of the soil, and holding the moisture that is stored in the root bed beneath this blanket so that it may constantly feed the growing plants. This new theory and practice of surface cultivation must commend itself to the practical farmer, since it checks evaporation, catches the rainfall and transmits it to the subsoil and destroys the weeds just as they germinate, thus leaving the whole wealth of fertility in the soil, and leaving also the entire equipment of plant roots unbroken, that they may feed upon this fertility and bring the crop to its fullest and largest perfection.

THE SILO.

By F. A. DERTHICK, Mantua, O.

The introduction of the silo as a factor in modern agriculture has not met with that general favor which its merits demand, and, although an increasing number of dairymen and stock raisers are availing themselves of the advantage of ensilage, the majority is still very large who cling to the older system of dry fodder. This is in part due to the extravagant claims made for ensilage by the early pioneers in the new departure. These enthusiasts insisted that, by some unknown and mysterious process taking place in the silo, the food value of the fodder was increased. Later scientific investigations exploded this fallacy, and thus suspicion was aroused against the system.

The advantages of ensilage have been found to lie in another direction, and that, instead of there being any addition to the food value, there is an actual loss brought about by the conversion of at least a part of the starch and sugar into various acids (lactic or acetic, or both). The Wisconsin Experiment Station after a study extending through a series of years now declares that there is a loss in the nutritive food value of 16 per cent. in both dry matter and protein as against a loss of 24 per cent. on the field dried fodder. It is evident that this slight difference will not in itself justify the outlay necessary for the construction of a silo.

The advantages of the silo may be summed up as follows: Silage furnishes a succulent summer food in winter, thus making it possible and profitable to produce milk during that season of the year when the market is comparatively bare of milk, cheese and butter. This feature alone will prove of incalculable benefit to the dairyman, as it will give a more uniform price for dairy products by withdrawing a part of the surplus of milk from the summer months. Again, the value of silage is supported by economic principles, as the complex changes going on in the silo render the food more digestible and easily assimilated; especially is this true in the case of corn silage. The effect of the moisture and heat of the silo is much like the cooking of food in so far as putting it in the very best condition to be digested. Many insist that the digestive organs of the animal are thus relieved to a greater degree than when the grain is taken to the mill and ground. Silage is also more palatable than dry food and is received with greater avidity by all kinds of stock accustomed to its use. The moist and softened condition of the coarser portions of the stalk, hitherto rejected in great measure, are thus laid under contribution to the food supply of the farm. This is in line with the findings of our scientific friends who claim that the lower portion of the stalk has as great feeding value as the corn itself.

It is not claimed that silage is a properly balanced ration, but it should be supplemented by some food richer in protein. Various tables are given by scientific men as constituting a formula in which the necessary constituents of a nutritive food ration are present. From a large number of inquiries, as well as from observation of the most successful dairymen, the following is suggested as a day's ration: Ensilage, 45 pounds; clover hay, 8 pounds; bran, 5 pounds; oil meal, 1 pound. Total, 59 pounds.

This ration can be furnished at an average of ten cents. There may be those who can figure the cost of the cow's daily keep on dry fodder at as low a point, but it will not be admitted that an equal flow of milk will result or that the animal will be in as good condition. If the above statements be true, they become very suggestive along economic lines. In these days of close competition and struggle to live, it becomes necessary to accomplish the greatest possible results from a given area of land.

A very successful siloist in Erie County gives the cost, including construction of silo, at $1.25 per ton. The silo he builds in the following manner: The studding are two by six, placed about twenty inches apart near the bottom and increasing the distance as the top is approached. These are securely fastened at the corners. Lining is composed of straight-edged boards, one by six, double thickness and breaking joints. Between the two linings is placed thick paper coated with tar. It is further secured by placing a strong beveled piece of timber in each corner, securely fastened. The bottom can be prepared by cementing, or if of stiff clay, used without.

The first silos erected were for the most part of stone or brick, and when stone is at hand it is a question whether such are not cheaper in the end, as they are practically indestructible, not being likely to spread with the pressure or be affected by the acid of the silage.

Numerous attempts have been made to create a prejudice against the silo by charging tainted milk from cows where silage was fed. This charge has never been sustained where the silage was bright and wholesome and fed in moderation. Many of our most fastidious consumers express their preference for silage milk.

A variety of green crops may be used as silage; clover, millet and the soja bean are said to give satisfactory results. It is to corn, however, that we must look for ideal silage. The leaming and mammoth ensilage are more often used than any other varieties. The pioneers made the mistake of cutting the corn too immature, thus missing the best results. The practice now is to cut when the kernel is dented and glazed, yet before fully ripe. In filling the silo, great care should be taken to pack every part of it closely. The corners should receive especial attention. The secret of good silage, like that of canned fruit, is in making it air-tight. The silo should be of such size that one day's feed will require at least two inches from the entire surface of the silo. Shallow silos are to be avoided, as the greater the depth is, the more pressure—a condition which is in every way desirable.

DENDROBIUM VICTORIA REGINA—FLOWERS SLATY-BLUE, WITH WHITE CENTER.

SOME ANATOMICAL PECULIARITIES OF THE HORSE.

By S. R. HOWARD, V.S., Hillsboro, O.

Microscopically considered, the structure and development of the bones of the horse are identical with those of man. His ribs number eighteen on each side, although occasionally he has more. I remember having seen a mule that had thirty-eight well developed ribs, nineteen on each side. The number of molar teeth is given as twenty-four, but I have seen twenty-eight well developed, perfect grinders doing duty. The skull bones, excluding the teeth and bones of the ear, are thirty-eight in number. The bones of a colt's head at foaling time are disarticulated. These, of course, become united in the adult. The skull of man and the skull of the horse are composed of exactly the same number of bones, having the same general arrangement and relation to each other—not only the individual bones, but the very ridges and surfaces for the attachment of muscles, and every hole for the passage of artery or nerve, seen in one can be traced in the other. We find in the adult male horse, midway between the grinders and the incisors, the four canine teeth. Occasionally they are seen well developed in the mare, but usually in her they are rudimentary, are often shed and never replaced. All mares, however, have the germs of them in the chambers of the jaws, and they appear in the majority of old mares. Some authorities claim they have known of these canine teeth in the male to be shed and replaced, but as a rule these teeth appear only in the male horse and are permanent from the time of their first appearance. While these teeth distinguish the sex, their loss would not be felt on that account. If Darwin is correct, these tusks are in the course of ultimate extinction. There is more or less mystery about these tusks, yet they are important factors in the consideration of the problem of the evolution of the horse as well as of other animals. Perhaps in the long ago these teeth served him as weapons of offense and defense.

THE ORANGE THEATER.

APROPOS of the representation of Antigone and the Eumenides recently given at the theater of Orange, a few words concerning ancient theaters, and particularly the one just mentioned, will, perhaps, not be out of place.

Generally speaking, an ancient theater, Greek or Roman, comprised two essential parts: an elongated rectangle designed for the actors and a semicircumference adjoining the longest side of the rectangle and designed for the public.

The long internal side of the rectangle formed the façade. In the Orange Theater this façade was preceded by a portico that is now destroyed, but which doubtless served as a promenade for the spectators and a shelter for the actors. The rectangle itself was divided into two parts. One of these, the proscenium, an elevated platform, extended from the tiers of seats set apart for the spectators as far as to the wall of the stage. Here stood the actors, the choruses and the flute players.

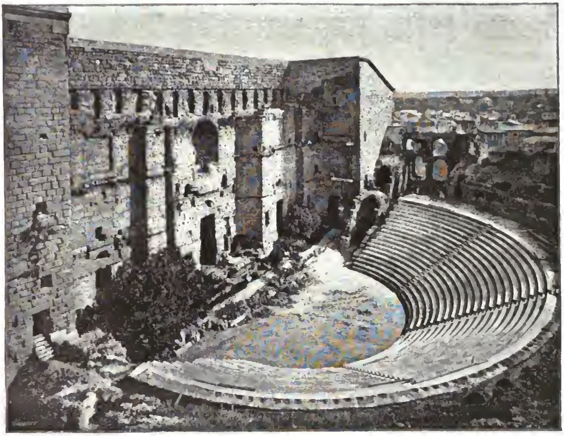
In the rear extended the postscenium, containing the side scenes and the actors' rooms. The stage was provided with three doors that permitted of passing from the proscenium into the postscenium, one of them (the royal door) being in the center and the two others at the sides. In front of the rectangle reserved for the actors unrolled the curtain, or aulaeum, which, instead of rising, as with us, descended at the beginning of representations.

The semicircle set apart for the public was called the cavea, and comprised two parts—at the periphery several tiers of seats and in the center a level part called the orchestra. The seats, to which access was sphinxes, of which fragments have been found. The orchestra was doubtless richly paved. The stage was sumptuously decorated. The central part, the aula regia, must, according to Vitruvius, have given the idea of a palace. In fact, at Orange, marble columns, statues, sculptures and mosaics were used in profusion. In the center of this internal façade, says M. Revoil, in a very interesting lecture, arises a two story motif, forming on the ground floor the aula regia, a large central door surrounded by columns with niches between. On the first story there was the same arrangement for surrounding the large niche in which was enthroned Marcus Aurelius, under whose reign this theater was probably constructed. To the right and left of this central motif extends a three story architectural decoration formed of three superposed Corinthian orders. This decoration is found again upon the sides of the two foreparts of the proscenium, and, on the ground floor, frames the lateral doors on the first and second stories and mosaic medallions over these doors. Friezes enriched with foliage, bass reliefs representing combats of centaurs, eagles, and various attributes added to the richness of the orders of architecture. The stage was protected by a vast sloping ceiling with gilded coppers, and the cavea by an immense purple curtain.

Such was doubtless the magnificent arrangement of the Orange Theater, when, in the second or third century of the Christian era, seven thousand spectators, clad in robes of dazzling colors, applauded the dramas of Sophocles, the comedies of Caecilius or the mimes of Laberius.

Since those fine days the Orange Theater has undergone many vicissitudes. The barbarians in the first place and the Calvinists in the second destroyed or gradually brought the stage and orchestra to light and permitted of the discovery of a large number of fragments. It may be said that he truly rediscovered the Orange Theater. So it is with complete justice that his bust was inaugurated here at the last fêtes.

Other architects have since continued his labors. M. Daumet has restored the cornice of the façade, which was crumbling away, and M. Formigé has occupied himself with the cavea. He has closed up the two apertures that existed to the right and left between the stage and the hall and which left too free a passage for the wind, and has also restored the tiers of seats. The first story, which comprises twenty rows of the latter, has been almost entirely rebuilt. The courses that support the second story are in way of repair. It was but natural that, in measure as the theater was repairing, the idea should occur to place it in a state to be used again for the purposes for which it was primarily designed. As long ago as 1840, M. Ferdinand Michel, a distinguished writer, thought of this, and tells us that at this period he often went to visit it. The keeper of the theater, who was a good declaimer, offered from the stage dramatic tirades that allowed him to judge of the admirable effects of the voice from every part of the auditorium. Gradually M. Michel began to dream but one dream, and that was of giving a representation upon this wonderful stage. This dream was not realized till thirty years later, on the 21st of August, 1869, when he caused "Joseph" (of Méhul) to be represented, along with a piece that he wrote for the occasion: "The Triumphers." In 1874, "Norma," "The Chalet" and "Galatea" were played, and in 1886, M. Mouzin had his "Emperor of Arles" represented twice in succession. It was then that were organized the admira-



VIEW OF THE ROMAN THEATER AT ORANGE.

obtained through arched corridors, were reserved for the public at large. Sometimes corporations or private individuals had their names engraved at the place that they occupied, just as is now done with a churchwarden's pew. One tier found in place in the Orange Theater bears the inscription EQ. G. III, that is to say, Equitum gradus tres, "three rows of knights."

The orchestra was set apart for people of eminence, the public authorities, and the Roman praetor, who occupied the center, seated upon his tribunal.

It is from such general data, obtained especially from Vitruvius and Pausanias, and from a thorough study of the ruins of ancient theaters and particularly the one under consideration, that Auguste Caristie, the eminent architect, has been able to restore the Orange Theater herewith represented.

The southern end of this theater is contiguous to the mountain. The structure is 77 meters in depth. The external façade forms a parallelogram 103 meters in length by 37 in height. On the ground floor this façade presents arcades of Tuscan order. On the first story there is a line of blind arcades, and above there is a solid wall that carries two rows of corbels designed to support the masts of the velarium, that is to say of the immense tent that protected the cavea. The Caristie restoration gives us a very accurate idea of this part of the theater. It comprised three tiers of seats separated by circular landings that served as passageways. Above the third rose a portico that was doubtless set apart for slaves and that crowned these tiers of seats. Between the orchestra and the proscenium extended a large passage parallel with the stage.

The first fifteen rows of seats ended at a wall with projections; upon the first row of which were seated damaged the Roman antiquities. Maurice of Nassau, who was as great a vandal as they, had a fortress constructed in 1622 from materials taken from the arch of triumph and the Orange Theater. A portion of the edifice was even inhabited by the princes of Orange and afterward converted into a prison. The principality of Orange was united in 1660 on French territory. In 1673 M. de Grignan, the son-in-law of Mme. de Sévigné, and then Lieutenant-General of Provence, had the castle of Maurice of Nassau razed. The theater, which served as an outer bastion, was then disengaged, and when Louis XIV came to visit the city he declared that the immense façade of the theater was the finest wall within his kingdom. In fact, it produces a feeling of surprise and admiration. As Mérimée well says, "For the principal elevation, the imposing effect of masses has been sought, and not a delicacy and exactness of details. Grandeur requires no ornaments."

Under the Revolution it was proposed to convert the stage into a vast dungeon, and Millin, the antiquary, was justly indignant at it. The government of the Restoration finally occupied itself with the ruins of Orange, and as long ago as 1824 Auguste Caristie was commissioned to ascertain the state of the theater, and after this restorations were carried on without any break. Constructions covered the whole interior of the edifice and adjoined the exterior; and the occupants had everywhere sapped the walls in order to enlarge the spaces that they had usurped. In certain places the walls had been pierced, and in others their thickness had been diminished by two-thirds. In the presence of the exigencies of these singular proprietors, it required a law to free the theater from these rats and ravens that had taken possession of it. Caristie's excavations ble representations of the month of August of 1888. Boudouresque sang the "Moses" of Rossini, and Mounet-Sully played the "Œdipus Tyrannus" of Sophocles, amid the inexpressible emotion of ten thousand spectators. The magnificent representations that have just taken place, the éclat of which was enhanced by the presence of the President of the republic, have made definitely of the theater a center of artistic and literary pilgrimages—a Bayreuth at once ancient and French.—Le Magasin Pittoresque.

The Russian Ministry of Finances has recently issued a report on the production of platinum in Russia, according to which that country stands first in the world for this production, forty times the quantity produced by all other countries together being obtained there. In the year 1880 the quantity produced amounted to 2,946 kg.; in 1895 it reached 4,413 kg. The production had gone on increasing up to the last year, when it diminished on account of the wet weather in summer. This rare metal is found exclusively in the southern Ural. The manner of its being worked up is unknown in Russia; this is done in Germany, to which country the platinum is exported in a crude state. Whatever Russia requires of worked up platinum it has to buy back from Germany. Of late years the price of this article has run very high: at present it is 900 marks (about £45) for 1 kg. of crude platinum in Russia. On mining for the platinum, the still rarer metal iridium is also found, but only in very small quantities. Last year the total quantity of iridium obtained did not amount to more than 4·1 kg., and this was only slightly exceeded in 1894.

THE SPREAD OF LAND SPECIES BY THE AGENCY OF MAN; WITH ESPECIAL REFERENCE TO INSECTS.*

By LELAND O. HOWARD, Ph.D.

AMONG the many influences which during the last century or two have been affecting that unstable condition of life which is expressed in the words "the geographical distribution of animals and plants," none has approached in potency the agency of man exerted both purposely and unwittingly or accidentally.

Natural spread was for centuries the rule. Species dispersed under natural conditions along the line of least resistance. Winged animals and seeds were spread by flight and by the agency of winds, and at their stopping places thrived or did not thrive, according as conditions were suitable or not suitable. Aquatic animals and plants and small land animals and plants were distributed by the action of rivers and streams and by the ocean itself. Wonderful migrations have occurred, commonly with birds, more rarely with other animals; ice floes and driftwood have carried animals and plants far from their original habitats and even volcanic action has taken part in the dispersal of species. Smaller animals, especially mollusks and insects, and the seeds of plants have been carried many hundreds of miles by birds and lesser distances by mammals.

With the improvement of commercial intercourse between nations by land and by sea another factor became more and more prominent, until in the present period of the world's history the agency of man in the spread of species, taking all plant and animal life into consideration, has become the predominating one. Potentially cosmopolitan forms, possibly even insular indigenes, have by this important agency become dispersed over nearly all of the civilized parts of the globe, while thousands of other species have been carried thousands of miles from their native homes and have established themselves and flourished, often with a new vigor, in a new soil and with a novel environment.

It is obvious that this agency is readily separable into two divisions: a, intentional; b, accidental.

a. Intentional Importations.—Since early times strange plants and animals have been carried home by travelers. Conquering armies have brought back with the spoils of conquest new and interesting creatures and useful and strange plants. With the discovery of America and with the era of circumnavigation of the globe, such introductions into Europe of curious and useful species, plants in particular, increased many fold, while with the colonization of America and other new regions by Europeans there were many intentional return introductions of old world species conducive to the welfare or pleasure of the colonists. Activity in this direction has been increasing and increasing. Public botanical gardens and many wealthy individuals in all quarters of the globe have hardly left a stone unturned in their efforts to introduce and acclimatize new plants, particularly those of economic importance and æsthetic quality, not failing occasionally, it must parenthetically be said, to establish some noxious weed or some especially injurious insect; while it is safe to say that probably the majority of the desirable plants of Europe which will grow in the United States have already been introduced, and that there has been an almost corresponding degree of activity in the introduction of desirable plants from the United States into Europe. In all this host of valuable introductions there have been comparatively few which have turned out badly, aside from failures of establishment. The wild garlic (Allium vineale), that ubiquitous plant which gives its taste to milk, butter, and even to beef during the spring and summer months in many of our States, is said to have been intentionally introduced by the early residents of Germantown, Pennsylvania. The water hyacinth (Piaropus crassipes), originally grown for ornament in a pond near Palatka, Florida, escaped into the Saint John's River about 1890, and has multiplied to such an extent as to seriously retard navigation and to necessitate government investigation. The distribution of the orange hawk weed (Hieracium aurantiacum) a dangerous species which has ruined hundreds of acres of pasture land in New York of recent years, was originally aided by a florist as a hardy ornamental plant. The European wood-waxen (Genista tinctorium) was early introduced at Salem, Mass., in fact about thirty years after the settlement of the colony. It has apparently not been used as a dye plant, but for garden and ornamental purposes only. During the last few years it has become a noxious weed throughout Essex and the adjoining counties. Standing on a rock at Swampscott on July 9 last, the writer was able to see that the country for miles around was colored a bright yellow with enormous masses of this plant. Similar instances are fortunately rare and the majority of our noxious weeds have been accidental introductions.

Intentional introductions of animals, however, have by no means resulted as advantageously as intentional introductions of plants, with the exception of the truly domesticated species, such as the horse, ass, cow, sheep, pig, dog, cat, poultry, honey bee and silkworm of commerce. Even with such species, the grazing ranges of Australia have been overrun by wild horses to such an extent that paid hunters shoot them at a small sum per head, and the European rabbit has become a much worse plague on the same island continent.

Intentional introductions of wild species, however, have almost without exception resulted disastrously.

At various intervals between 1850 and 1867 a few pairs of English sparrows were introduced into our Northeastern States to destroy canker worms, and today this species is a ubiquitous and unmitigated pest throughout all the austral and transition regions of North America, finding its limit only at the borders of the boreal zone, while the place of the injurious insect it was imported to destroy has been taken by another and worse insect pest which it will not touch.

In 1872 Mr. W. Bancroft Espeut imported four pairs of the Indian mongoos from Calcutta into Jamaica for the purpose of destroying the "cane-piece rat." Ten years later it was estimated that the saving to the colony through the work of this animal amounted to £100,000 annually. Then came a sudden change in the aspect of affairs. It was found that the mongoos destroyed all ground-nesting birds, and that the poultry as well as the insectivorous reptiles and batrachians of the island were being exterminated by it. Injurious insects increased in consequence a thousandfold; the temporary benefits of the introduction were speedily wiped away, and the mongoos became a pest. Domestic animals, including young pigs, kids, lambs, newly dropped calves, puppies and kittens were destroyed by it, while it also ate ripe bananas, pineapples, young corn, avocado pears, sweet potatoes, cocoas, yams, pease, sugar cane, meat and salt provisions and fish. Now, we are told, Nature has made another effort to restore the balance. With the increase of insects due to the destruction by the mongoose of their destroyers has come an increase of ticks, which are destroying the mongoos, and all Jamaicans rejoice.

The flying foxes of Australia (Pteropus sp.) are animals which are very destructive to fruit in their native home. Frequently some well-meaning but misguided person will arrive on a steamer at San Francisco with one or more of these creatures as pets. While it is not probable that any of the flying foxes will thrive in northern California or in fact in austral regions, the experience is too dangerous to try, and the quarantine officer of the California State Board of Horticulture has always destroyed such assisted immigrants without mercy.

Less than thirty years ago (in 1868 or 1869) Prof. Trouvelot imported the eggs of the gypsy moth (Porthetria dispar) into Massachusetts. The insect escaped from confinement, increased in numbers, slowly at first, more rapidly afterward, until in 1889 it attracted more than local attention, with the result that in 1890 the State began remedial work. This work has steadily progressed since that time and the State has already expended something over a half million of dollars in the effort to exterminate the insect, and it is estimated that one million five hundred and seventy-five thousand dollars more must be used before extermination can be effected.

Contrast with this a single intentional importation which has had beneficial results. The Australian ladybird (Vedalia cardinalis) was introduced into California in 1889, with the result of saving the whole citrus growing industry of the State from approaching extinction through the ravages of the cottony-cushion scale (Icerya purchasi). Later importations of the same insect into South Africa and Egypt also resulted beneficially.

We have thus had sufficient experience with intentional importations to enable us to conclude that, while they may often be beneficial in a high degree, they form a very dangerous class of experiments, and should never be undertaken without the fullest understanding of the life history and habits of the species. Even then there may be danger, as with a new environment habits frequently change in a marked degree.

b. Accidental Introductions.—The agency of man, however, has been more potent in extending the range of species, and in changing the character of the faunas and floras of the regions which he inhabits by means of accidental importation.

The era of accidental importations began with the beginning of commerce and has grown with the growth of commerce. The vast extensions of international trade of recent years, every improvement in rapidity of travel and in safety of carriage of goods of all kinds, have increased the opportunities of accidental introductions, until at the present time there is hardly a civilized country which has not, firmly established and flourishing within its territory, hundreds of species of animals and plants of foreign origin, the time and means of introduction of many of which cannot be exactly traced, while of others even the original home cannot be ascertained, so widespread has their distribution become.

These accidental importations would at first glance seem to have been more abundant with plants than with animals, since the opportunities for the carriage of seed, especially flying or burrlike seed, and especially when we consider the vitality of this form of the plant organism, are plainly manifold, but I shall later show that possibly even this obvious generalization must be modified in view of the multitudinous chances for free travel which the smaller insects have under our modern systems of transportation.

The agencies which have mainly been instrumental in the accidental distribution of plants are:

1. Wind Storms.—It is obvious that light flying seeds may be carried many hundreds of miles by hurricanes, and may fall in new regions.

2. Water.—This is a very important agency in the distribution of plants upon the same continent, but less important as affecting intracontinental distribution. Still they may be carried by this means from one island to another adjoining island, and when lodged in the crevices of the driftwood, they undoubtedly travel greater distances.

3. Birds.—Seeds are frequently carried great distances by birds. Many of the larger seeds will germinate after passing through the alimentary canal of a bird, and may thus be eaten at one point and voided with the excrement at a widely distant point. It has been shown, for example, that the local distribution of Rhus toxicodendron is greatly affected by the carriage and distribution of the seed in this way by the common crow. Smaller seeds are carried in earth on the feet of birds. Darwin's example of a wounded red-legged partridge which had adhering to its leg a ball of earth weighing 6½ ounces, from which he raised 82 plants of about 5 distinct species, is an evidence of the possibilities of this agency, while his experiment with 6¾ ounces of mud from the edge of a pond which produced 537 distinct plants, an average of a seed for every 6 grains of mud, is still more conclusive.

4. Ballast.—This is the first of the distribution methods which may be combined under the head of "agency of man." The discharge of earth ballast by vessels coming from abroad has been a notable means of distribution of plants by seed. We have just seen how many seed may germinate from a very small lump of earth, and the possibilities in this direction of the many thousands of pounds of discharged ballast are very great. In fact, the ballast grounds in the neighborhood of great cities are invariably favorite botanical collecting spots; they have usually a distinctive flora of their own, and from these centers many introduced plants spread into the surrounding country.

5. Impure Seed.—The great industry in the sale of seed which has grown up of late years is responsible for the spread of many plant species, principally, it must be said, undesirable species. Mr. L. H. Dewey says: "It may be safely asserted that more of our foreign weeds have come to us through impure field and garden seeds than by all other means combined."

6. The Packing Material of Merchandise.—The hay or straw used in packing crockery, glassware or other fragile merchandise is a frequent carrier of foreign seeds. Such goods frequently reach the retailer without repacking, and the hay or straw is thrown out upon the fields or used as bedding for domestic animals and carried out with the manure.

7. Nursery Stock.—Plants are often accidentally introduced by means of seeds, bulbs and root stocks attached to nursery stock or among the pellets of earth about the roots of nursery stock. The extraordinary development, of late years, of commerce in nursery stock has undoubtedly been responsible for the intracontinental carriage of many species of plants in this way.

Instances of the accidental spread of larger animals by man's agency are necessarily wanting. Of the smaller mammals the house rat and the house mouse have been accidentally carried in vessels to all parts of the world and have escaped and established themselves, the former practically everywhere except in boreal regions, or only in its southern borders, and the latter even as far north as the Pribyloff Islands, as I am informed by Dr. Merriam. Small reptiles and batrachians are often accidentally carried by commerce from one country to another, but although there are probably instances of establishment of such species, none are known to me at the time of writing.

Land shells are often transported accidentally across the ocean in any one of the many ways in which the accidental transportation of plants and insects may be brought about, and by virtue of their remarkable power of lying dormant for many months are able to survive the longest journeys. The conditions which govern the establishment of species in this group, however, seem somewhat restrictive; whence it follows that comparatively few forms have become widespread through man's agency, although Binney mentions a number of European species which have been brought by commerce into the United States and have established themselves here, mainly in the vicinity of the seaport towns of the Atlantic coast.

With the earthworms a striking situation exists. It has been shown that, "without a single exception, the Lumbricidæ from extra-European regions are identical with those of Europe; there is not a variety known which is characteristic of a foreign country."* Careful consideration of the evidence seems to show that this is due to accidental transportation by the agency of man.

Comparatively little has been done in the study of the geographical distribution of insects. In the words of Wallace:

"The families and genera of insects are so immensely numerous, probably exceeding fiftyfold those of all other land animals, that for this cause alone it would be impossible to enter fully into their distribution. It is also quite unnecessary, because many of the groups are so liable to be transported by accidental causes that they afford no useful information for our subject, while others are so obscure and uninteresting that they have been very partially collected and studied, and are for this reason equally ineligible."

Nevertheless, the time has already arrived with some groups, and is not far distant even with the others which Mr. Wallace has termed "obscure and uninteresting," when, owing to the indefatigable industry of entomologists as a class, important facts can be gained along distribution lines from the group of insects. Thus it is only within the past few months that the publication of Mr. W. F. Kirby's "Catalogue of the Odonata of the World" has made it possible for Mr. G. H. Carpenter, of the Royal Dublin Society, to prepare a comprehensive paper on the geographical distribution of the dragon flies, a group in which a comparatively few workers have interested themselves. It is in a measure true to-day, as it was entirely true when Wallace wrote, that "many of the groups are so liable to be transported by accidental causes that they afford no useful information for our subject," yet even with the group in which the greatest obscurity as to the original home of the species has existed, owing to a very easy and most frequent commercial transportation—the Coccidæ or scale insects—the continued discovery and characterization of new forms from all parts of the world, and especially of those existing in wild regions, away from the influence of man, are gradually giving us an insight into the probable character of the original coccid faunas of more or less restricted regions.

By reason of the drawbacks mentioned, Wallace considered only "a few of the largest and most conspicuous families which have been so assiduously collected in every part of the globe, and so carefully studied at home as to afford valuable materials for comparison with the vertebrate groups." These groups included 16 families of diurnal Lepidoptera and six of the families of Coleoptera. Even with this restriction among the beetles, however, he must have had some difficulties with the accidental importations, for among the beetles are hundreds of examples of this class of introductions. For example, writing later in his "Island Life," the great naturalist shows that in 1880 the total number of species of beetles known in the Azores amounted to 212, of which 175 were European. Out of these, however, no less than 101 were believed to have been introduced by human agency. Concerning St. Helena he quotes Mr. Wollaston's opinion that 78 of the 203 species have certainly been introduced by the agency of man.

(To be continued.)

Preserving Rubber.—The tendency of becoming brittle which India rubber shows may to some extent be modified by immersing the article in question in a 3 per cent. solution of carbolic acid. Tubing, stoppers, etc., will stand several years' wear without much damage if this precaution is observed.—Der Stein der Weisen.

* Paper read before the Zoological Section of the American Association for the Advancement of Science, August, 1897. A portrait of Doctor Howard will be found in the SCIENTIFIC AMERICAN of even date, page 193.

ENGINEERING NOTES.

Messrs. Burmeister & Wain, of Copenhagen, have recently built in their yard an ice breaker, which has broken all records by cutting through ice 22 ft. thick, extending over a mile, says Engineering. The Nadeshny, as she is called, belongs to the Russian government, and will be stationed at Vladivostock. Her length is 180 ft., beam 43 ft., her displacement equals 1,500 tons when 18 ft. in the water aft and 13 ft. forward. With engines indicating 3,000 horse power, a speed of 14½ knots was attained on her trials. The Nadeshny's frames are closely placed and of extra heavy section, the plating being ¾ in., ⅝ in. and 1 in. steel, with considerable tumble home of both sides and ends. Water tanks fore and aft allow considerable alteration of the trim, and by this means the stem can be brought up so as to draw only 9 ft., while the stern can be put down to 22 ft.

Radhanpur is a small native state in North Gujarat, and is at present governed by a British administrator, the nawab being a minor. The state authorities are anxious that their capital may be connected with the outer world by a railway, and are willing to pay for such length of it as will lie in their own territory. It is expected, says Indian Engineering, that surveys will be carried out early next season, with a view to ascertain to what point on the existing railway systems the proposed line from Radhanpur shall be carried. The points so far suggested are Viramgam, on the Bombay, Baroda, and Central Indian Railway's Wadhwar branch, Patan on the Patan branch of his highness the Guekwar's Mehsana Railway, and Deesa on the Palanpur Deesa Railway. It is expected that the necessary surveys will be carried out by the Bombay, Baroda and Central India Railway Company.

The newly constructed ironclad Petropavlovsk will be a valuable addition to the Russian navy, and will prove to be the most powerful vessel in the Baltic fleet. The body of the ironclad has been built in St. Petersburg, on Galerny Island. The armor plates are nickel steel, 10 in. thick, and were prepared in the Ijora Works. Larch wood has been principally used in the construction of the vessel, but her deck is partly of fir and partly of teak. The entire ship's length, including the ram, is 375 ft., the maximum breadth is 70 ft., and the mean draught 25½ ft., and her displacement amounts to 10,960 tons. She is twin screwed, with triple expansion engines of 10,600 indicated horse power, built in England by the firm of Hawthorne, Leslie, & Company. It is calculated that the ship will have a speed of 17 knots. Her armament will consist of four 12 in. heavy guns and twelve 6 in. breechloaders. Besides these, she will carry some Hotchkiss quick firing guns. Four torpedo tubes have already been mounted. Since her stern draught will not permit of her heavy guns being mounted in St. Petersburg, on account of the shallowness of the Neva and the canal, she will shortly proceed to Cronstadt to complete her armament there. It is hoped that the Petropavlovsk will be ready to undergo her trials at the end of September or the beginning of October.

The Aeronautical Journal for July contains among other features an article on "Flight and Flying Machines," by Major Fullerton, R.E., from which we have taken the following: "There are really only two kinds of flight, viz., soaring flight and driving flight, and it is desirable to consider them separately. In soaring flight the only forces acting on the body are its weight and the air; no artificial force acts on it; and flight of this class is based solely upon skillfully combining the weight and air forces. As a consequence, no artificial force whatever, or, in other words, no power, is required for soaring flight, and provided the wind—or air force—is suitable, and proper arrangements are made for combining it with the force of the weight, there is nothing to prevent this class of flight being carried on indefinitely without any artificial aid whatever. In driving flight the conditions are different. Here two forces have to be developed, viz., the sustaining and the driving force. The most suitable way of doing this seems to be to use either a large sustaining surface, as done by Maxim, or to construct the machine on the lines of Phillips, and use a large number of small surfaces, something like the slats of a Venetian blind. Then, in order to sustain the body in a horizontal path, and drive it along with constant velocity—Sustaining force (vertical component of the air force) = weight = W, driving force = horizontal component of the air force = R, and the power required to drive and sustain the body at constant velocity $V = \frac{RV}{550}$ H. P., using the ordinary units of measurement."

The first successful apparatus of which we have any knowledge that burned fuel without the production of smoke was invented by Abu Musa Dschabir Ben Haiyan—better known by the name of Geber—an Arabian alchemist, who lived about the end of the eighth century. He is credited with the discovery of nitric and sulphuric acids, and of certain preparations of mercurial and other metallic salts. Geber called his furnace the Tower of Athanor, and from its construction a steady and uniform heat could be maintained for an indefinite period. Its principal feature, according to Mr. W. F. Durfee, in the Journal of the Franklin Institute, was a high cylindrical tower for containing the fuel. This tower was flanked by two combustion chambers, in or over which the substance or vessel to be heated was placed. These chambers were connected with the central tower near its base by flues, in which were dampers for regulating the flow of the gas generated from the fuel. This furnace of Geber was in fact a "gas furnace," and the general principles involved in its construction were the same as we see in everyday use in all self-feeding base burning stoves, and in many gas furnaces for metallurgical purposes; in fact, many of the so-called improved gas producers are no better and but slightly different from that invented by Geber over 1,000 years ago, and he must be regarded as the discoverer of the great advantages resulting from converting solid fuel into a combustible gas, and then burning that gas in a combustion chamber separate from that containing the solid fuel. Geber's furnace was not a mere suggestion, but was in common use by chemists in all well-appointed laboratories until the beginning of the present century.

ELECTRICAL NOTES.

A railway is to be exhibited at Paris (France) in 1900 which differs from the present style of railways in this respect, that the cars do not move on the rails, but the rails themselves are moved over fixed wheels. The wheels are driven by electricity. A stop must be made for each passenger who wishes to get in or out. The railway will probably be constructed as an elevated road.—Zeitschrift für Architectur.

Electric motor cars are to replace steam locomotives on the Chicago & South Side Elevated Railroad, and when this change is made all the elevated railways in Chicago will be operated by electricity. Work has been commenced laying the third rail under the direction of Mr. E. Klapp, chief engineer, and it is expected that the third rail and feeder cables will all be laid on the structure by the end of November. In the Sprague system of electric traction, which has been adopted, each car will have its own motors, all the cars of a train having electrical couplings, so that the entire train is operated from the front car. On all the other elevated lines the front car only is fitted with motors, and is thus an electric locomotive, the other cars not being equipped with power.

The electric tramways in Dresden are equipped with Siemens & Halske's electric brakes. These brakes act upon the car axle, which is not driven by the electric motor. They are fixed both upon the motor car and upon each of the trailers, and act simultaneously. It is claimed that these brakes act in about one-third of the time of the hand brakes. Trials with both show that the electric brake stopped a car going at a speed of fifteen miles per hour within fourteen yards, while a car with a hand brake going at twelve miles per hour traveled thirty-five yards after the brake was applied. The same electric brakes are used for the line Behrenstrasse-Treptow, at Berlin, says the Electrical Engineer. In this case the brake acts upon the motor direct, and there is no brake upon the trailing carriages. When going at the usual speed these cars are stopped within eight yards.

Although there are several plans to the fore in Sweden about important electrochemical manufactories, to which the abundant water power lends itself admirably, says London Engineering, there are not yet many in operation, the most important being the one for manufacture of chlorate of calcium at Mansbo, where the process used is the one patented by Mr. O. Karlson. The Mansbo waterfall represents the aggregate power of about 5,000 horse power, of which, to begin with, only a small portion was utilized. There were 8 turbines of 230 horse power each, revolving at a speed of 360 revolutions per minute; they have horizontal axes and are directly coupled with their dynamos. The normal capacity of the latter is 1,200 amperes, 115 volts, and they are being worked both day and night. The machines work independently of each other. The current is conveyed from the dynamos to the electrodes, of which the one is of carbon, the other of iron. The original output was fixed at 650 tons per annum, but this has been found altogether inadequate. The installation has, therefore, been extended very materially, and now represents 3,000 horse power and an annual output of some 1,300 tons. The whole installation has cost rather more than $400,000, the cost of machinery and plant being about equal to that of the necessary constructions which were required in order to utilize the water power.

An electric tramway installation is being laid down in Brisbane under the supervision of Mr. J. S. Badger on behalf of the General Electric Company of America. According to the Electrician, the track is laid on sleepers and is chiefly double, the rails weighing from 55 pounds to 83 pounds per yard and bonded with the Chicago bond. The total mileage is about 25½ miles of single track, the furthest point being distant 5,683 yards from the power station. The overhead trolley system is being employed, with side poles and span wires. No. O. B. and S. copper wire is employed for the trolley wire and the majority of the poles are of iron. The feeders are run overhead and are 500,000 circular mils. The boilers are of the Babcock-Wilcox type, and work at 170 pounds steam pressure. The engines are Robey's horizontal compound condensing, with trip gear. The engines have cylinders 17⅝ in. and 30⅝ in. by 40 in. stroke, and are designed for a most economical load of 450 indicated horse power, with 150 pounds steam at the stop valve. They are coupled by leather belting 36 in. wide and 30 ft. centers to General Electric multipolar generators. These generators are of the four-pole type, over-compounded from 500 volts at no load to 550 volts at full load (350 amperes). The cars are propelled by two motors of the General Electric type—25 electrical horse power each—which are fitted to the car with a nose suspension. The cars are fitted with ordinary hand brakes and series parallel controllers.

A very clever mail delivery box has been placed in a number of the larger buildings at Geneva, Switzerland, by an enterprising electrician. This mail box has a compartment for each of the stories of the building, and when the letters are deposited on the ground floor, the carrier delivers them as required. The deposit of a single letter makes an electric contact, which starts a bell going on the respective floor, which does not cease ringing until the letter is taken out. At the same time it opens the faucet of a tank on the roof of the house, which causes water to flow into the cylinder forming the counterweight of the mail box elevator until the weight is heavier than the box, when the box ascends and the flow of water ceases simultaneously. As the box passes each story the mail intended for it—letters, papers and small packages—falls into boxes in the corridor on that floor. This is performed very reliably by a little spring at the bottom of each compartment in the elevator mail box, which causes the bottom of the compartment to catch for a moment, and the release throws out even a single piece of paper thinner than a postal card into the stationary box provided for its reception. When the box has passed the uppermost floor the cylinder filled with water strikes a bolt provided at the bottom, which allows the water to flow out, and by its own weight the box descends to its place on the ground floor. Should by any mischance a single piece of paper have remained in the elevator, upon striking the bottom it will at once go through the same series of movements as before.

MISCELLANEOUS NOTES.

Berlin, the German capital, had its first sidewalk in 1827, on the "Breite Strasse." A private individual put it down before his house, and was honorably commended for his conduct by the king.—Monatsschrift für den Oeffentlichen Baudienst.

Siemens & Halske propose to treat gold-bearing stibnite by dry chlorination, lixiviation with water drying and again subjecting to the action of chlorine gas. After a second lixiviation, the gold is supposed to be mostly in solution. The residue is then treated with HCl, whereby the antimony is converted to chloride, which is dissolved, and the solution electrolyzed, metallic antimony and chlorine gas being produced. The gold is precipitated from the first solutions by electrolysis, or any practicable method.

The Northwestern Lumberman says that a new industry has arisen in Michigan, namely, the conversion of pine stumps into shingles. It is stated that stumps of trees which were cut twenty to twenty-five years ago remain enduring and obdurate obstructions to the cultivation of the soil. They are still sound and turn out excellent shingles when so utilized. This shows the lasting quality of white pine. In the early days of lumbering in Michigan the tree was cut high from the ground, and these old stumps which the farmers are cutting into bolts represent the method of that period. In later years, economy in a material which had become too valuable to waste dictated the cutting of stumpage as near the ground as possible.

The value of foreign books imported into Germany has risen from $2,000,000 to $5,000,000 in the thirteen years from 1881 to 1896. The figures for 1896 are as follows:

Austria-Hungary	$1,800,000
Switzerland	800,000
France	700,000
Holland	400,000
England	400,000
Russia	180,000
United States	158,000
Various other countries	560,000

If we except Austria-Hungary and Switzerland, which publish many works in German, we find that France stands first in the list.—La Vie Scientifique.

How is it that the British exports of Portland cement to the United States have dwindled so much during the last twelve months? For the year ending 1896, the imports in the United States from England amounted to 297,000,000 lb., while for the year ending May, 1897, they were only 174,000,000 lb. In these two periods the imports from Belgium remained nearly stationary, falling only 3,000,000 in a total of 237,000,000, while Germany's contribution has fallen only 73,000,000 in a total of 482,000,000. In other words, while Belgium's trade has diminished less than 2 per cent. and Germany's only 15 per cent., our trade has been reduced nearly 42 per cent., says The Builder. If this reduction is due to increased activity in the building and engineering trades at home, there is no cause for complaint; but if it is due to the better quality and cheaper prices of foreign cement, it is high time that British manufacturers made an effort to regain the lost ground.

The invention of frieze is claimed by a historian of the Netherlands to have been made by the inhabitants of that country, says the Trades Journal Review. They were famous for their A friser or napped cloth. It is possible that the name of the material may have come from its having first been made in Friesland. Later the name was applied to linen, for in 1641 we find, says Fiber and Fabric, linen of frieze mentioned, and in 1671 under the head of linen, "frieze cloth." It appears to have been very early an Irish product. In 1399 "frieze of Coventry" is mentioned. In the sixteenth century this cloth came to be more generally adopted. It is spoken of by one author as a coarse kind of cloth manufactured in Wales, "than which none warmer in winter, and the finest sort thereof very fashionable and genteel. Prince Henry had a *frieze* suit made." An act of 1551 refers to frieze as a Welsh manufacture, and mentions counties which were specially noted for its making. At that time it was made in finer qualities than we usually associate with the material, and men of the highest rank had clothing made of it.

At a recent meeting of the Société de Statistique, Yves Guyot made the following interesting statements concerning industry and commerce in France, says The Engineer. Of French exports, 90 per cent. fall to foreign countries, 10 per cent. to the Colonies. The value of the French home trade amounted to 7,200,000,000 francs in 1896, or 187 francs per head of population, which is about the same as in Germany. The value of the English imports to France amounts to 500,000,000 francs, and the value of exports from France to England 1,053,000,000 francs. Belgian imports to France, 282,000,000 francs; ditto exports, 501,000,000 francs; German imports, 307,000,000 francs, ditto exports, 339,000,000 francs; United States imports, 1,313,000,000 francs; ditto exports, 224,000,000 francs. These four countries consume 61 per cent. of the total French exports, while England alone consumes no less than 30 per cent. On the whole, 7,271,500 tons, worth 3,401,000,000 francs, have been exported, and 22,619,000 tons, worth 3,700,000,000 francs, have been imported to France.

The New York Prison Association will hold an exhibition of articles made by convicts and of prison appliances in its rooms at 135 East Fifteenth Street on October 7, 8 and 9. The exhibition will be divided into groups. In the historical section will be shown pictures and plans of prisons, relics of famous jails and of criminals and crimes. The gallery of portraits of prison keepers and reformers will form part of this section. In another group will be shown models of cells, apparatus used in punishments and executions, police appliances, and forms and blanks showing the organization of prisons. The other sections will be made up of drawings and charts representing criminal types and peculiarities, publications on penology, instruments used in making identifications, literary and artistic work of convicts, and articles made by prisoners. There will be a series of conferences between prison workers while the exhibition is open. Dr. H. E. Allen, the superintendent of the asylum for the criminal insane at Matteawan, will read a paper on insane criminals.

PREVENTING MILK TURNING SOUR.

As soon as the true causes of milk and cream becoming sour or otherwise deteriorating in flavor became known, scientists set to work to discover some means of destroying the bacteria without at the same time injuring the milk. Chemicals of various kinds were tried, but there are objections to the use of all of them. The most successful of all methods of preserving milk and cream yet discovered are those known as pasteurizing and sterilizing. The latter of these is necessary only when milk and cream have to be kept sweet for weeks and months. The two operations, though alike in principle, yet differ in degree. In both, heat is applied to the milk or cream, but not to the same extent. In pasteurization it is necessary to raise the temperature to between 150 to 175 degrees F., and keep it there for about twenty minutes to destroy all active bacteria present. In sterilizing, the temperature must reach or exceed 212 degrees F., that is boiling point. The objection to sterilizing is that it gives a burnt flavor to the product. The pasteurizing process, if properly conducted, leaves no perceptible difference in the taste. As both processes accomplish the object of keeping milk perfectly sweet for a longer period than it would otherwise do, it is clear that for dairying operations pasteurization is preferable to sterilization. The great advantages of treating all cream for butter making by pasteurizing it does not, it is stated by Mr. S. Lowe, seem to be fully recognized in the colonies. In Denmark and Sweden more than 90 per cent. of the butter exported is made from pasteurized cream. During the very hot weather in the Australasian colonies the necessity for this process is most imperative. Artificial refrigeration cannot repair the injury already done to milk or cream by the growth of bacterial life; it can only prevent further injury. If the evening's milk has not been rapidly cooled and kept so during the night, it swarms with bacteria when brought to the factory in the morning, many of them being of the baneful variety, and the cream should be carefully pasteurized; that is, the bacteria should not only be prevented from further increase—they should be killed right off. If the factory manager allows even one farmer's cream which is swarming with evil bacteria to mix with the sweet cream of the rest of his supplies, he will soon discover that the proverb of "ill weeds grow apace" is as applicable to the cream vat as to the garden.

Let us now explain how pasteurization keeps milk sweet for a much longer time than it would otherwise do. The minimum multiplying point of most milk bacteria may be taken at 50 degrees F., the maximum at 113 degrees F. Between these points they multiply in various degrees of rapidity. Thus, while bacteria can live from below zero to about 150 degrees F., they can only multiply from 50 degrees to about 113 degrees F., the temperature most suitable for their growth being 80 degrees F. to 100 degrees F. From this it follows that, if milk be kept below 50 degrees or above 113 degrees, the bacteria in it cannot multiply, though those already existing can at these temperatures carry on their processes of converting the sugar of milk into various acids. Hence, if milk be already swarming with bacteria, it is best to raise the temperature to such a point as will kill them right off, and this temperature, we have seen, is 150 degrees and upward. We have given the pasteurizing temperature as 150 degrees to 175 degrees F. Above this there is danger of producing the burnt flavor previously mentioned. At 150 degrees it takes longer to kill the bacteria than at 175 degrees. At 155 degrees twenty minutes will do, at 160 degrees fifteen minutes, at 165 degrees ten minutes, and so on. Pasteurizing, however, does not kill all bacterial forms. It destroys those that propagate by fission only. It does not kill those that multiply by spores. The baneful kinds, unfortunately, are those which mainly breed by spore formation, and hence are more difficult to kill. In fact, only a sterilizing temperature is sufficient for this purpose. Herein lies a great danger. Unless pasteurized milk is rapidly cooled down to a temperature at which these spores become torpid, pasteurizing is very dangerous, for there is every probability that all the beneficial bacteria will have been killed and only the baneful ones remain alive. Therefore, artificial cooling process must be used along with pasteurization if the best results are to be obtained.—Gardeners' Magazine.

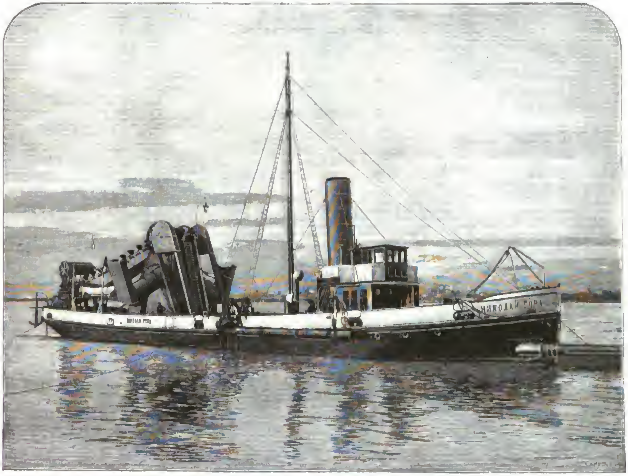
A SUCTION AND BUCKET DREDGER.

THE dredger of which we reproduce two photographs has been constructed by Messrs. A. F. Smulders, of Rotterdam, for use in the ports of the Sea of Azov. It is a suction and bucket dredger, and is provided with two centrifugal pumps for discharging the material dredged up either into barges brought alongside or directly on to the banks. The vessel is 151 ft. long by 27 ft. 3 in. wide, and is 10 ft. 6 in. deep. The maximum draught is about 7 ft. and the speed when fully loaded 8·5 knots. The vessel is constructed in accordance with the requirements of the first class of the Bureau Veritas. It can dredge to a depth of 22 ft. under water, and cuts its own way in the banks. The principal framework of the dredging apparatus is of tubular construction, made of plate 30 in. thick, and angles 3 in. by 3 in. by 0·4 in. The sternward feet of the frame are carried to the bottom of the vessel, the others rest upon a stout beam at the level of the deck. The dredging ladder passes centrally through the vessel, which is divided at the stern for this purpose. It is propelled by twin screws driven by two compound surface condensing reversing steam engines, each of 200 horse power—French. The same engines work the two discharge pumps. The high pressure cylinders are 15 in. diameter, the low pressure cylinders 26¼ in. in diameter, and the stroke is 15¾ in. The dredging ladder is driven by a similar engine. Two marine boilers supply steam at seven atmospheres for these engines. The total heating surface is about 2,300 ft. These boilers, and a small vertical boiler for providing the electric light, etc., are constructed of mild Siemens-Martin steel, and conform with the dimensions required by the Bureau Veritas. At port and starboard there are coal bunkers of 1,765 cubic feet capacity.

The discharge pumps can discharge about 8,830 cubic feet of sand or sandy mud per hour at a distance of 550 yards, raising it to a height of 5 ft., between the discharge orifice and the water level. These pumps will also raise spoil from a depth of 22 ft. by means of a tube lowered at the side of the vessel. Under these conditions it can raise and deliver into barges alongside or at a distance by means of floating pipes at least 8,830 cubic feet of sand per hour. The suction tube can be withdrawn entirely from the water, so that no resistance is offered to the sailing of the vessel.

On the deck is situated all the necessary maritime paraphernalia, and the hoists for raising the dredging ladder. The dredges are lighted exteriorly by two arc lamps, and within by incandescent lamps, and the cabins are heated by steam pipes.—The Engineer.



SUCTION AND BUCKET DREDGER.

PERPETUAL MOTION.—IV.*

The celebrated astronomer, James Ferguson, F.R.S., devised the machine illustrated in Fig. 17. It is but fair to state, however, that the machine was designed to show the fallacy of perpetual motion schemes. Ferguson never believed it would move, but maintained that its immobility was a full demonstration of the utter impossibility of a self-moving device.

The axle is placed horizontally, and the spokes turn in a vertical position. The spokes are jointed, as shown, and to each of them is fixed a frame in which a weight, D, moves. When any spoke is in a horizontal position, the weight, D, in it falls down, and pulls the weighted arm, A, of the then vertical spoke straight out, by means of a cord, C, going over the pulley, B, to the weight, D. But when the spokes come about to the left hand, their weights fall back and cease pulling, so that the spokes then bend at their joints and the balls at their ends come nearer the center on the left side. Now, says Ferguson, "as the balls or weights at the right hand side are farther from the center than they are on the left, it might be supposed that this machine would turn round perpetually. I have shown it to many who have declared it would; and yet, for all that, whoever makes it, will find it to be only a mere balance. I leave them to find out the reason."

An old note informs us that "between the years 1700 and 1780 London abounded with perpetual motion seekers and their public exhibitions." Ferguson himself, a mechanician and inventor, would, no doubt, visit many of them, and would see "schemes ingenious, curious, and specious." He did not believe it possible to produce perpetual motion by any contrivance which required the motive power to be within itself (all external agents, such as that of a never-failing stream, the ever-varying pressure of the atmosphere, etc., being ignored). Yet, notwithstanding that, in 1770 he devised this plan for perpetual motion. In his "Commonplace Book," we find a fine pen and ink drawing of his scheme, which he designates as "the most rational scheme," but at the same time declares it to be "downright nonsense." At the conclusion of it he writes: "Whoever makes it will find that it is a mere balance;" from this it may be inferred that the machine was never made—never having had any other existence than that on paper.

W. Stephen claims our notice for drawings which he has left us of his designs for perpetual motion through applications of magnetism, and also of capillary attraction, which we can, however, only treat as early misconceptions, and offer them as a warning against pursuing similar attempts, for it is evident that if such schemes as those were capable of proving anything, the proof could only relate to the perpetuity of the agent, and not of the mechanism sought. A feather retained in a constant current of air would prove quite as much, that is, the constancy of the current as opposed to the inconstancy of the mechanical arrangement when rendered independent of such external agency. Stephen's sketches occur on the paper lining of the backs of a small quarto, entitled "Le Machine," by G. Branca, 1629, in the English Patent Office Library, having a fly leaf inserted on which is written, "W. Stephen's Book, March 10th, 1799."

His first figure, Fig. 18, has the following written on one side of it: "Motion by Magnetism. W. S.—Rep: per duobus N idem tempore quod cessit Attr: apud ☞ et sic aliter et de etc."

That is, the repulsion is twice through N in the same time that the attraction ceases at the ☞, and so on the contrary. This notice is obscure enough, but the next, Fig. 19, marked "Magnets at the end of spiral springs," appears without comment. We can only surmise, therefore, that Stephen expected that the magnet, N, on attracting an opposite magnet, or steel bar, would overweight the wheel, and thus continually present one after the other in succession, in like manner, thereby causing a continuous rotation!

From the works of the Hon. Robert Boyle, vol. v, page 71, we copy an historical account of a strangely self-moving liquor:

An ingenious teacher of mathematics, having occasion to make a composition for a new fire engine, wherof he was to show his Majesty a trial, mingled divers ingredients in an earthen pot over kindled coals; but could not or did not do it so warily, but that the matter took fire, and began to blaze furiously, which obliged him to stifle the blaze as hastily as he could; and having removed the vessel from the fire and suffered it to grow cold, when afterward he came to look upon it, to see if what remained might be of any use to him, he was surprised to find it variously and briskly moved. Wherefore, having set it aside, to be sure that it might be thoroughly cold, he, after some hours, visited it again, and found it move as before; and having cast store of seeds upon it, to see if the liquor would move them also, the bituminous part of it connected them into a kind of thick scum, that covered most of the superficies, but yet left some intervals in which the liquor appeared, and discovered that it continued its motions. Two days after, the engineer discoursing with me of this fire work, about which he had advised with me before, told me, among other things, of this odd accident. And when I asked him if the motion continued still, and had been answered affirmatively, though it was then a dark night and ill weather, my diffidence or my curiosity made me engage him to send for the pot as it was, partly to be sure of the matter of fact and partly to try if the knowledge I had of the ingredients, which he had before told me, would afford any hint of the cause of so odd an effect; a like to which in kind, though not in degree, I had many years before devised, and successfully practiced, the way of producing.

The vessel being come, though the hasty transportation of it seemed to have sufficiently disturbed it, there did appear manifest signs of such a motion as the engineer had ascribed to it, and, therefore, he being willing to leave it with me, I caused it to be set aside in a laboratory, where some furnaces kept the air constantly warm, and did there and elsewhere, at different times, look heedfully upon it, now and then displacing or quite taking off some of the thick scum that too much covered the surface of it, and by this means I had the opportunity to take notice of several phenomena, whereof these are the chief:

1. I observed that the motion of this liquor was not only brisk, but very various, so that having loosened some small portions of the scum, one of them would be carried toward the right hand for instance, and another toward the left, at the same time.

2. Where the liquor first came out from under the scum, it seemed to move the most briskly, flowing almost like a stream whose motion upward had been checked, and, as it were, reverberated by that incumbent obstacle.

3. Several motions in this liquor were the more easy to be observed, because, though it were dark, yet it was not uniform; consisting in part of oily and bituminous ingredients, which, though they seemed to have but one common superficies with the rest of the liquor, yet, by their colors and power of vigorously reflecting the light, they were easily enough distinguishable from

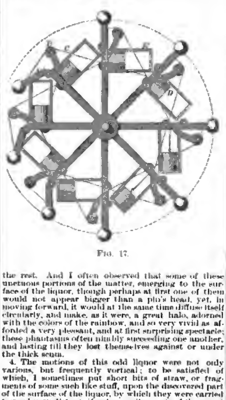

Fig. 17.

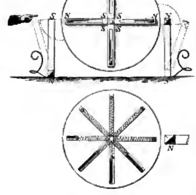
the rest. And I often observed that some of these unctuous portions of the matter, emerging to the surface of the liquor, though perhaps at first one of them would not appear bigger than a pin's head, yet, in moving forward, it would at the same time diffuse itself circularly, and make, as it were, a great halo, adorned with the colors of the rainbow, and so very vivid as afforded a very pleasant, and at first surprising spectacle; these phantasms often nimbly succeeding one another, and lasting till they lost themselves against or under the thick scum.

4. The motions of this odd liquor were not only various, but frequently vortical; to be satisfied of which, I sometimes put short bits of straw, or fragments of some such like stuff, upon the discovered part of the surface of the liquor, by which they were carried toward very distant, if not opposite, parts of the vessel at the same time. But to make the vortical motion more evident, I several times detached considerably large pieces of the thick scum from the rest of the body, and had the pleasure to see them move both



Figs. 18 and 19.

with a progressive motion in crooked lines, and with a motion about their own middlemost parts. All this while the liquor, whose parts were thus briskly moved, was actually cold, as to sense.

5. To observe what the presence, or absence, of the free air would do to this liquor, I caused many spoonfuls of it, with some of the scum, to be put into a cylindrical glass, which, though large itself, had a neck belonging to it that was but about the bigness of one's thumb, that it might be well stopped with a cork. But having, by this means, kept the free air from having a full and immediate contact with the whole surface of the mixture, as it had when that mixture lay in the wide mouthed vessel, I could not perceive the liquor to move to and fro, no, not though the orifice of the neck were left open; whereas, having, at the same time, poured some of the liquor into a very shallow and wide mouthed vessel, called in the shops a clear caked glass, it moved rather more than less nimbly and variously than in the great earthen pot (which yet was of the same shape), and showed as many of those vivid and self-dilating circles that have been mentioned in the third number; and these, by the fineness of their colors and the quickness wherewith they succeeded one another, afforded a delightful spectacle as long as I stayed to observe the liquor.

6. Though the motions of the hitherto mentioned liquor did not seem to be always equally brisk, yet they appeared to continue manifest and various in some diversities of weather, as to cold and heat, and when I looked on it by candle light as well as by daylight; and when, not being well enough to visit it myself, I sent one purposely to look upon it, about ten o'clock at night, he brought me word that it continued to move as formerly, and so it has done for ten days; and how much longer it will continue to do so, time must determine.

Postscript.—Some time after the foregoing account had been written, when I came to look upon the liquor (which in the mean time had been several times viewed, and appeared to retain its motions), I found, to my trouble, that somebody's impertinent curiosity and heedlessness had cracked the lower part of the earthen pot; at which overture, the liquor, though not the scum, was run out; which had put a period to our observations, but that, foreseeing that such an accident might happen, I had long before taken out some spoonfuls of the liquor, and kept it close stopped in a vial. By this means I had the opportunity to observe that, when I poured out the liquor into a wide mouthed vessel, it would move as before, though this were done some weeks after it had been put up. And I remember that long after, having one day received the honor of a visit from a foreign minister, who was an inquisitive person and a man of letters, we chanced, among other things, to talk of the liquor; and though it were scarce to be hoped that it could retain any of its motive virtue, yet, to gratify his curiosity, and that of some ingenious men there present, I caused the vial to be brought, and having unstopped it, I poured out the liquor into a convenient shaped vessel, in which, after we had suffered it to rest awhile, they were delightfully surprised to see it move (though not, in my opinion, quite so briskly as before), yet very manifestly and variously. This encouraged me to think it possible that it might retain some motion, though but languid, seven or eight weeks after; and therefore, on the 25th of July, I looked upon it again, and having caused it to be poured into a china cup, it manifested, at first, a brisk and various motion; but this, after awhile, did so slacken that I began to have some suspicion that the motion it was put into by effusion and the first contact of the air might have given it the greatest part of its agitation. But this being but suspicion, I put the vessel into divers postures in a window, the better to discover the true cause of this phenomenon; but while I was busy about this, which engrossed my attention, a mischance overturned the cup, and, by throwing down the liquor, put an end to my speculation; yet this mischance hindered me but from observing how long the odd agitation of our liquor would have continued, but not from finding that it lasted a great while; for I showed it to the foreign minister about or after the beginning of June, that is, about five months or more after the liquor was first observed to move.

Innumerable are the devices by which men have sought to make wheels permanently retain an excess of weight on one side of their centers, while revolving. Our engraving, Fig. 20, illustrates one of these absurd attempts. An endless chain, A, passes over pulleys, B, over the idler pulley, D, and under the idler pulley, C. It is expected that the increased weight of the greater length of chain on one side of the upper pulley, B, will more than counterbalance the weight of the chain on the other side, and also compensate for friction created by the pulleys, and so impart a constant rotation to the pulleys and fly wheel.

The device described is, however, outdone by the one shown in Fig. 21, prepared in 1829, by a correspondent of the Mechanics' Magazine.

This was to be a self-moving railway carriage. The genius who devised this machine thus writes in regard to it:

"In treating of perpetual motion—'that grand secret for the discovery of which those dictators of philosophy, Democritus, Pythagoras, Plato, did travel unto the Gymnosophists and Indian priests'—it would add considerable interest to give some account of its early history. Regarding the fallibility of every contrivance hitherto planned or experimented upon, we may gather sufficient from the writings of Bishop Wilkins alone. The 'little world' of Paracelsus and his followers; the planetarium invented by Cornelius Drebbe, for King James; the 'magnetical globe of Terella,' suggested by Pet. Peregrinus, with the wheel that he, Taisner, and Cardan thought might be kept in motion by 'pieces of steel and loadstones,' are, like the Bishop's own wheel and plummets, and his application of Archimedes' screw, inadequate to the grand end for which they were designed.

"Without enlarging on this head, we shall proceed with the description of a machine which, were it possible to make its parts hold together unimpaired by rotation or the ravages of time, and to give it a path encircling the earth, would assuredly continue to roll along in one undeviating course till time shall be no more.

"A series of inclined planes is to be erected in such a manner that a cone will ascend one (its sides forming an acute angle), and, being raised to the summit, descend on the next (having parallel sides), at the foot of which it must rise on a third and fall on a fourth, and so continue to do alternately throughout.

"The diagram is the section of a carriage, with broad, conical wheels, resting on the inclined plane. The entrance to the carriage is from above, and there are ample accommodations for goods and passengers. The most singular property of this contrivance is, that its speed increases the more it is laden; and when checked on any part of the road, it will, when the cause of stoppage is removed, proceed on its journey by mere power of gravity. Its path may be a circular road formed of the inclined planes. But, to avoid a circuitous route, a double road ought to be made. The carriage not having a retrograde motion on the inclined planes, a road to set out upon, and another to return by, are indispensable.

"I am indebted to a much respected friend for the

* Reprinted from the Scientific American, 1870-71.

hint of this means of effecting a veritable perpetual motion."

"The Perpetual Motion Hunter" is the title of an article in the Imperial Magazine, vol. 6, 1824:

It gives me much pleasure (says the writer) to observe that you notice scientific subjects; you are very right in so doing, as it will not only give variety, but add considerably to the value of your very useful miscellany. It is my humble opinion that such a procedure is infinitely better than filling it with the splenetic effusions of angry minds, the ebullitions of disappointed envy, or, what is worse, dealing out large portions of scandal, and making use of personalities to wound virtuous sensibility, as is the constant practice in some similar publications.

I am now, sir, an elderly man, and am sorry to inform you that I have lost much valuable time, and, of course, money, too, from having been infected, in the early part of my life, with the vanity of hunting after that ignis fatuus called the "perpetual motion." Common report informed me that it would immortalize the name of the inventor; that by it the longitude would be discovered; and that, on this account, the British Parliament had offered a premium of ten thousand pounds for its discovery! This was something like assailing a man at all points at once; the acquirement of such prodigious fame flatters his vanity; and the "ten thousand pounds" could be looked upon in no other light than as the reward of distinguished genius!

Under these impressions I began my career, and pursued it with an ardor which, in any other case, could not have failed to insure me success. I read with the greatest avidity all the accounts of such machines I could anywhere meet with. For a short time I was amused with the ball of iron and the magnet, mentioned in Bishop Wilkins' "Mathematical Magic." I afterward studied the properties of Orffyreus' wheel, which, as Gravesande informs us, continued in rapid motion for two months; at the end of which period it was stopped, he says, to prevent the wear of materials. This astonishing wheel was, you know, destroyed by the inventor, soon after the time of the above mentioned experiment. I endeavored with all my might to recover the long lost secret, and success partly crowned my efforts; for, after a great deal of wearisome labor, I constructed a machine which I then believed would amply compensate the loss which the crazy philosopher had occasioned, when, in a fit of frenzy, he dashed it to pieces. The delight which Newton felt, on discovering the law of gravitation, did not exceed mine when I found that my machine would answer the intended purpose. 'Tis true, it would not put itself in motion—but what then? It was sufficient for the purpose if it would move perpetually when put in motion; and at that time, like many others, I did not quite understand how many requisites were necessary in order that a machine might become a "perpetual motion."

You can scarcely imagine how my heart palpitated when I sent off a description of this, my first invention, to the Board of Longitude. It was a machine which I had no doubt would determine the longitude, both at sea and land, with the greatest ease and accuracy. During the first week, my nightly slumbers were frequently broken by the violent perturbations of my mind; and my day dreams almost continually represented to me the postman knocking at my door with the wished-for letter that was to crown all my hopes. So certain was I of success that I actually began to look about for an estate which the ten thousand pounds were to purchase; for, in my mind's eye, I had it already in my grasp. The humble occupation I had till then followed I now looked upon with disgust; and I saw myself at once elevated to opulence and fame. I waited with patience—yes, Mr. Editor, with all the patience I could muster—but no letter arrived. However,

> "Day presses on the heels of day,
> And moons increase to their decay."

After a few weeks, my mind recovered its wonted serenity, and in about three months more my machine was as free from any violent perturbations as my mind, for at the end of that period, it had completely lost all power, either of perpetuating or continuing its motion. This circumstance occasioned me some uneasiness; and I was not much amused with the taunting remark of one of my friends, who on viewing it exclaimed, "Well! it is a perpetual motion still!" At the end of nine months, I received a letter from the Secretary of the Board of Longitude, informing me of what I already knew—namely, that my machine would not answer.

It is now carefully stowed in my brother Jonathan's garret, at Brigg, in Lincolnshire, where it may be seen by all who are curious in such matters.

I now turned my mind into a different channel. I thought it possible that the object of my search might be accomplished by means of some of the fluids. I considered, with care, the almost continued oscillation of the mercury in the tube of the barometer; but I could deduce from this motion no practical result. I afterward endeavored to turn the tides to some account; but I failed here also. At length, after turning my mind in a variety of ways, as I was one day reading an account of the rise of water in capillary tubes, it at once occurred to me that, as the water rises in such a tube to more than an inch above the surface of the water in the vessel in which the tube is immersed, if I placed the tube in an inclined position, the water would run over its top; and as it would fall into the same vessel, the motion thus produced would be perpetual. At this moment my mind was again agitated; I exclaimed, like Pythagoras, "I have found it! I have found it!" I now supposed myself to be as great a man as any Pythagoras that ever lived. I did not, however, run out, like him, naked into the street; but I remember the discovery was made in the winter season, when I was warmly and comfortably clothed. Had it been in the summer, I cannot tell what might have happened.

I soon procured a capillary tube, and proceeded very carefully to make the experiment; but the water did not flow! Well, said I, this is curious; but a siphon will run: that the water does not run from the top of the tube is owing to the pressure of the atmosphere upon it. I now ordered a capillary siphon, and was again disappointed; for the sluggish water, as if envious of my fame, still refused to move.

Having recovered a little from the stupor into which I had been thrown by the failure of another of my schemes, it occurred to me that if I employed a siphon to carry water over the bank of a river that communicated with the sea, the siphon would run if the outer leg on the outside of the bank was longer than the inner leg; and because the water would find its way into the ocean, and be brought back by the process of evaporation, which is constantly going on, the motion would be perpetual. I could not, however, employ this method to discover the longitude, either at sea or land, and, of course, I was not entitled, from this invention, to the ten thousand pounds.

Another of my machines consisted of two wheels, A and B; the wheel, A, had a number of buckets, at equal distances, round its outer rim. These buckets were so placed that they would each contain a ball of iron. Seven such balls were always on one side of the wheel,

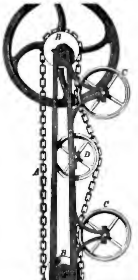


FIG. 20.

A, urging it downward; and one was in the inside of the wheel, B. When the wheel, A, had arrived in a certain position, the lowest ball fell out of its bucket, and rolled down an inclined plane, placed for that purpose, into the interior of B; and then it rolled down another inclined plane into the top bucket of the wheel, A, and so on. This machine had a very specious appearance, and was mistaken for a perpetual motion by thousands of well-informed persons. I need scarcely add that the persons I mention were ignorant of the laws of motion and the theory of mechanics. A similar machine was lately exhibited for a perpetual motion, and a great deal of money made by showing it to the good people of New York, in North America.

My last invention of this kind consisted of an iron wheel and four magnets, similar to the one exhibited some time back in Edinburgh and other places. As the wheel did not move uniformly, and as the power of the magnets soon began to diminish, I suspected it would ultimately fail, and abandoned it altogether. It is necessary to inform you that my modesty—or, rather, my honesty—would never permit me to exhibit any of my inventions for money, as I had always very strong

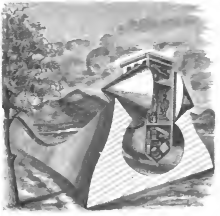

FIG. 21.

grounds of suspicion that they would not answer, and my suspicions were always verified in a short time. It was only after a great number of disappointments that I began seriously to think on the subject. I at first wondered how it happened that my schemes should always prove abortive; but I soon discovered that I was entirely ignorant of the theory of mechanics. Not long after, I had also the mortification to perceive that I had totally mistaken the specific nature of the machine which had been so long the object of my search; so that it would have been next to a miracle if I had found it. I now began in earnest to acquire a knowledge of the principles of natural philosophy, and I very soon found that I had begun at the wrong end of my business.

My misfortunes had created in me serious musings. Yes, said I, in all ages mankind have had some favorite object to pursue—a something bordering on the limits of impossibility. Astrology, or the foretelling of future events, was once the grand charm that led men astray. People are fond of prying into futurity. All men are naturally delighted with what is wonderful; and what pains do they take to deceive themselves! Astrology ruled with despotic sway during the reign of ignorance; but, as knowledge advanced, the chimera retreated; and the few votaries it has now left are ranked either among the most ignorant or the most knavish of all the human race.

Alchemy was another favorite pursuit. To be able to transmute the baser metals into gold was certainly an object of the greatest consequence, and now the discovery would be particularly desirable. There is no doubt that it would be liberally patronized by the ministers of state and the members of the British senate; because, if properly managed, it would enable them to pay off the national debt, and ease the good people of England of the intolerable burden of taxation. In case of such an event taking place, what joy would be diffused throughout the whole of this great empire! The people would be wealthy, and the ministers again able to create places and to give pensions ad infinitum. But I must return to my subject. The search after the perpetual motion is of the same nature as those of astrology and alchemy. It has long amused the ignorant and deceived the credulous; but men of science, properly qualified to judge of its merits, look upon it as a nonentity, and laugh at its proselytes as deluded creatures, who are pursuing a phantom of their own creation.

I have not much hope of being able to convince those persons who are in search of this shadow of a shade that their labors will be fruitless. I will proceed, however, to describe the machine they are endeavoring to construct. The perpetual motion is a machine which possesses within itself the principle of self-motion, and because every body in nature, when in motion, would continue in that state, it follows that every motion, once begun, would be perpetual, if it were not acted upon by some opposing force, such as friction, the resistance of the air, etc. In order, then, to produce a perpetual motion, we have only to remove all the obstacles which oppose that motion; and it is obvious that if we could do this, any motion whatever would be a perpetual motion. But how, let me ask, are we to get rid of these obstacles? Can the friction between two touching bodies be entirely annihilated?—or has any substance yet been found that is void of friction? Can we totally remove all the resistance of the air, which is a force continually varying? And does the air at all times retain its impeding force? They cannot be removed, then, so long as the present laws of nature continue to exist, and who will attempt to destroy them? Besides, it is a well known principle in mechanics that "no power can be gained by any combination of machinery, except there be at the same time an equal gain in an opposite direction;" and must there not be some absolute loss arising from opposing forces, as friction, etc.? How, then, can a perpetual motion be found by any combination of machinery? Another necessary circumstance is, that the motion of any such machine be uniform; for, if it accelerate, it will in time become swift enough to tear itself to pieces; if it retard, it will at length stop. Now, among all the numerous forces acting on machines—forces, too, which are continually varying according to known causes, and to the influence of which every machine is constantly liable—who is there so hardy as even to imagine that a machine can be constructed the motion of which shall be constant and uniformly the same?

There is one perpetual motion, and but one—that is, I know of but one—and that was constructed by Infinite Wisdom. The Divine Creator of the universe has balanced this earth with such exquisite art that its diurnal revolutions are performed so precisely in the same time that it has not varied the hundredth part of a second since the time of Hipparchus, which is now more than two thousand years.

All that we can hope is, that the beams of science will diffuse truth more generally through the world; for, otherwise, dreamers of every kind will continue to dream to the end of time.

(To be continued.)

THE WORLD'S GOLD PRODUCTION.

IT is only twenty years ago, says the New York Journal of Commerce, that an eminent European geologist startled the world by announcing the following conclusions: 1. That the production of gold in the future would have to depend mainly on the output from alluvial deposits. 2. That much more than one-half of the quantity of gold obtainable by the means hitherto employed had already passed through the hands of man. 3. That the time would certainly come, and probably after a few centuries, when the production of gold would cease to an extraordinary extent, and when that metal, on account of its ever-increasing scarcity, would cease to be able to maintain the economic position it had hitherto held. The figures of production seemed to sustain these conclusions. In 1871 the value of the gold mined throughout the world was about $127,000,000; by 1879 it had decreased to $116,000,000; in 1887 was within $106,000,000, and even in 1890 it fell short of $119,000,000. During this time the production of silver was advancing by leaps and bounds. Reckoned at its coining value, the world's production of silver in 1871 was $61,000,000; by 1879 it had touched $96,000,000; by 1887, $124,000,000; and in 1890 it was $162,000,000.

It was not only the discoveries of gold in South Africa that gave a new impulse to the world's production of that metal after 1887. The application of improved processes of separation, both mechanical and chemical, which had done wonders for silver production, was destined to accomplish still more notable results in the increased yield of gold. The cyanide process of gold extraction, which consists in dissolving the gold from ore, concentrates, or tailings by leaching (or agitation) with a dilute solution of cyanide of potassium and precipitating the gold with metallic zinc, dates from 1890. The cost of operating this process was originally $2.40 per ton of ore in bulk, but it was steadily reduced to $1.80 per ton, and has finally reached $1 per ton, and even lower. This and the cognate process of chlorination rendered it possible to work at a profit veins of gold in the sedimentary rocks whose existence, while not un-

known, was regarded as having no practical bearing on the supply of the precious metal. It is very largely due to the application of these processes that it has been possible so to utilize the refractory ores that the world's product of gold in the last seven years has grown from $130,000,000 in 1891 to $180,000,000 in 1894, and now to an estimated $240,000,000 in the present year.

To-day more than 60 per cent. of the world's production of gold is obtained from the solid rock—a proportion not likely to be seriously affected by the yield of British Columbian and Alaskan gravels. The mines of the Rand are producing at the rate of $12,000,000 more this year than they did last, and those of Australia promise to exceed last year's product by nearly $7,000,000. In both cases the sources of supply is almost exclusively crude ores, whose reduction is a question of capital and labor applied in much the same systematic way as prevails in more familiar departments of mining industry. Thus, from being one of the most hazardous of enterprises, gold mining has become one of the safest possible pursuits. The fact has been quoted as indicating the change of public sentiment in regard to the working of the auriferous strata of the earth's surface that established dividend-paying gold stocks four or five years ago might be bought at prices netting the investor from 25 to 30 per cent., while at the present time these same stocks command prices at which the investor realizes only 10 or 15 per cent. In fact, gold mining is being rapidly raised from the level of pure speculation to that of legitimate industry, and as an expert authority has pointed out, with this change has come that careful attention to small economies and to minor improvements in methods and appliances which marks all sound industrial operations.

Under such conditions the only limit to the world's production of gold is the cost of extracting the metal from its baser accompaniments. A tremendous advance was made when the hitherto worthless pyrites which could not be treated by amalgamation were made to yield up their gold contents to chlorination, and when it became possible by the introduction of the cyanide process to obtain almost the last traces of gold from the "tailings" which had been hitherto treated as mere rubbish. The director of the United States mint has stated that under the improved processes of ore treatment only 5 per cent. of the gold is lost. This is not literally true, referring as it does only to the ore crushings ready for chemical treatment. There is scientific authority for the statement that there is a possibility of enlarged profits from increased efficiency equal to an increase of yield of from 15 to 25 per cent. over that attained by the processes in use. The possibility, however, of enlarged profits from the combined effect of reduced working cost and increased efficiency is not arbitrarily limited to any percentage. At the close of last year Mr. Becker, of the United States Geological Survey, found, after actual study of the conditions existing in the Transvaal, that the cost of working a ton of ore might be reduced to about 25 shillings, though the actual minimum was still considerably higher. According to a return of the average yield of ore made by the various companies operating in the Rand, it appears that the amount of gold extracted from a ton varies from 5 pounds sterling to 16 shillings and 6 pence. About a fourth of the companies show a yield per ton of over 42 shillings; there is another fourth below the average, running all the way down to 33 shillings; between that and the point where there appears to be no profit nearly another fourth are operated, and the remaining fourth seems to be worked, so far, either at a positive loss or without any profit at all. The fact remains that there is in the mines of the Transvaal at least $1,500,000,000 of gold yet to be extracted, and that this includes considerably less than one quarter of the known available supply of the world, even before the recent discoveries at Klondike.

ON A SLOW COMBUSTION ARC LAMP SUITABLE FOR FACTORIES AND STREET LIGHTING.*

By W. S. Squire, Ph.D., F.C.S.

According to Mr. W. H. Preece, one-half of the cost of arc lighting is due to the consumption and replacement of the carbons. If in respect of this expense an economy of 50 per cent. could be realized, an important step in advance would be made, still more so, if an economy of 75 per cent. could be obtained. The lamp I am about to introduce to your notice goes much further than that, as you will see presently.

In an ordinary arc lamp the consumption of carbons is usually at the rate of about 1½ in. per hour—1 in. for the positive or upper carbon and ½ in. for the negative or lower carbon, or, say, 40 mm. per hour, both carbons included. This, of course, will vary somewhat, according to the amount of the current. The consumption of carbons in the new lamp (varying also with the strength of the current), and consuming the same amount of electrical energy as the ordinary arc lamp, will be from 1·30 to 2 mm. That is to say, only 5 per cent. of the consumption of the ordinary lamp—an economy of 95 per cent. As this result has been attained by means partly of a mechanical, partly of a chemical character, I thought it a fit subject to bring before a society occupied to a great extent with questions of chemical engineering.

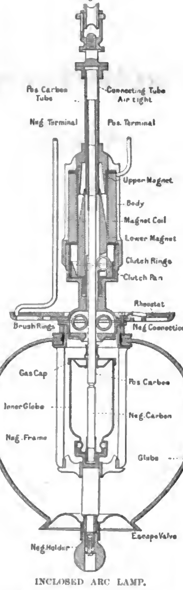
The lamp was invented by an American named Jandus, born in Wisconsin, of Hungarian parents.

I propose in the first place to describe the mechanical construction of the lamp, giving you an opportunity of handling and examining the various parts. I will then have the parts put together, so that you may see the same lamp in action. While this is being done we can consider the chemical side of the question.

Fig. 1 represents the lamp in section. The current enters the lamp by the negative terminal, and then passes through a resistance which has the effect of reducing the voltage (which is in this room 108) down to 81. This is about double the voltage usual for arc lamps. It then passes by the insulated screw shown on the right hand to the lower carbon holder, and so to the lower carbon. It crosses the arc to the upper carbon. It leaves the carbon by the brush rings, and then goes through the magnet coil to the positive terminal.

The magnet coil incloses two cast iron magnets, which I may call the male and female magnets. The female magnet is fixed, but the male is free to move up and down. These will have a tendency to attract one another, and when the current in the coil is strong enough to enable the induced magnetism to overcome the weight of the lower magnet this will rise, carrying with it the upper carbon. The effect of this will be to lengthen the arc, and by increasing the resistance, to diminish the current through the coil, and so arrest the further rise of the magnet. Matters thus remain in equilibrium until, by consumption of the carbon, the arc becomes longer, and the current thereby diminished. The lower magnet then begins to descend. It will be seen that both the fixed and the movable magnet are hollow, and that the upper carbon is not attached to either of them. How then does the movable magnet carry the carbon with it? This is one of the most ingenious contrivances in the lamp. There are three equidistant slots in the lower magnet. In each slot a brass ring is inserted, the rings being prevented from falling out by a wire passing round the magnet. The tendency of these rings is to fall together and clip anything passing in a downward direction, but they will allow anything to pass in an upward direction. By this means the carbon is firmly attached to the lower magnet.

Fig. 1.



INCLOSED ARC LAMP.

If, however, the magnet drops so far that the rings come in contact with a brass plate cut out so as to fit into the slots in the magnet, they are lifted and rolled back so as to allow the carbon to slide down by its own weight between the rings; the moment the normal current is re-established the magnet rises, the rings clutch the carbon, and its further movement is arrested. It is in this way that the upper carbon is gradually fed forward.

A somewhat similar device is employed to make an electrical contact with the upper carbon by means of the brush rings. These do not clutch the carbon at all, but rest gently against it, and being hung in such a way that they are free to turn, they make electrical contact without opposing any sensible resistance to the movements of the carbon. Moreover, they are so placed that the electrical contact is at no great distance from the arc, so that the carbon offers a minimum of resistance, and it is also an unvarying resistance—a point of some importance.

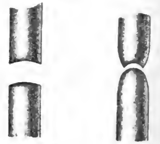
As shown in the drawing, the arc is produced inside a small glass cup, which is closed at the top by the so called "gas cap." This cap has a double duty to perform. In the first place it prevents to a considerable extent the escape of the gases resulting from the combustion of the carbons inside the cup. In the second place it provides for automatically extinguishing the lamp when the upper carbon is nearly exhausted.

The carbon passes freely through the aperture in the center of the cap, but the brass carbon holder cannot pass. As soon as this arrives at the cap the movement is arrested, the feed is stopped, the lamp is extinguished, and no harm can happen to the metal work.

Besides the small glass cup in which the arc is produced there is also an outer globe, which is so fastened by packing to the body of the lamp as to be quite airtight. In this way a layer of highly heated gases is caused to float in the upper part of the outer globe upon the colder gases beneath. This tends to assist the action of the gas cap in keeping the air from the arc. Lastly, the outer globe is closed at the bottom by an escape valve, which opens to let out the gases when expanded by the heat of the arc. Of course, this valve is removed when the carbons are renewed.

It is evident that the arc is produced in a small chamber, to which the possible access of air is reduced to a minimum. Consequently, very little combustion of the carbons takes place. After the lamp has been at work for a short time, almost all the oxygen present in the glass cup has been consumed, and the gases in the cup are found to have the following composition:

Fig. 2.



INCLOSED ARC. OPEN ARC.

Carbon dioxide	1·4
Carbon monoxide	23·6
Oxygen	2·7
Nitrogen	72·3
	100·0

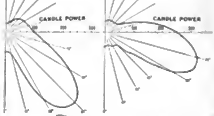
The interior chamber is not, however, perfectly airtight, and diffusion will occur between the gases in the interior chamber and those in the globe outside. Consequently, a very slow combustion of the carbons will go on, while, on the other hand, the gases produced in the interior chamber will diffuse into the outer globe. After some hours' burning the gases in the outer globe are found to have the following composition:

Carbon dioxide	0·8
Carbon monoxide	12·2
Oxygen	12·9
Nitrogen	74·1
	100·0

It is obvious that, in order to produce this effect, the tube in which the upper carbon, with its holder, slides must be perfectly airtight, and the joint between the glass globe and the lamp must also be airtight.

The result of this arrangement is that the carbons burn away very slowly, the consumption never exceeding 2 mm. an hour.

Using carbons of 13 mm. diameter, the upper one having a length of 270 mm., or, say, 10½ in., and the lower one a length of 150 mm., or, say, 6 in., the lamp is found to burn—



OPEN AIR ARC. INCLOSED ARC.

		Hours.
With a current of 4 ampères		220
" " 6 "		160
" " 7 "		120

Consider what this means! When the ordinary arc lamps are used, a man must go up the post every morning and put in fresh carbons. In the case of a lamp burning 220 hours it will be necessary to renew the carbons, on an average, only once in three weeks, say, once a fortnight in winter and once a month in summer. This is not only a great saving in carbons but in wages as well.

The lamp which we have put together has now been burning for about 10 minutes, and the gases in the interior chamber or cup should have the composition I have indicated. I will quickly remove the lower carbon and cup. At the moment that I do so, the highly heated upper carbon as it passes out should set fire to the gases in the cup (experiment performed). You see the carbon monoxide burning with the characteristic blue flame.

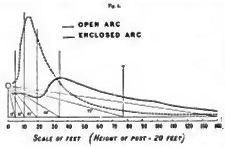
I wish to direct your attention to the way in which

* Paper read before the Society of Chemical Industry. From the Journal of the Society of Chemical Industry.

these carbons burn. In the case of the ordinary arc lamp burning in air, the consumption of the positive carbon, as compared with the negative carbon, is as two to one. In the case of the Jandus lamp it is as four to one, so that the consumption of the lower carbon is practically a negligible quantity. Owing to the lower carbon, in the case of an arc produced in air, burning away at about half the rate of the upper carbon, which is in all lamps fed up to the arc, the point of light is gradually lowered in the globe, so that any devices, such as reflectors, or holophane globes, soon cease to act properly unless there is a special compensating mechanism, usually both complicated and costly. Owing to the very small consumption of the lower carbon in this lamp, the luminous point is practically fixed without any compensating mechanism whatever.

There is also a considerable difference between the shape of the ends of the carbons burning in air and those burning in the Jandus lamp (see Fig. 2). In the Jandus lamp they remain very nearly flat, slightly convex on the negative, slightly concave on the positive. When the carbons burn in air the negative is very distinctly pointed, while there is a sort of crater formed on the positive. This is generally attributed to a transfer of the particles of carbon from one pole to another, but, of course, the forms produced in this way must be perpetually broken down and obliterated by the burning away of the carbons. When there is little or no burning away, as is the case with the Jandus lamp, we should expect to find this production of a point and a crater greatly accentuated, and in an exaggerated form. Nothing of the kind, however, happens; both the carbons remain practically flat, without point or crater. Perhaps we shall have to modify our previous conceptions in regard to this matter.

We have still to consider the distribution of the light over a considerable space of ground. You will say perhaps that the light diminishes according to the square of the distance. Yes; that is quite true of a white hot ball, like the sun, but it is very far from true of the light of the electric arc. The light emitted in one direction is very much greater than that in another direction, and it depends very much what that direction is. Mr. Hesketh, of Blackpool, has been experimenting, both with the Jandus lamp and with an arc lamp burning in air. Figs. 3 and 4 give his results in a graphic form. You will notice that an arc lamp, burning in air, shoots down its rays in such a way that the maximum is attained at an angle of 45° from the perpendicular, while the Jandus lamp attains its maximum at about 75°, that is to say, only 15° from the horizontal. Consequently, while the ordinary arc lamp



brilliantly illuminates objects almost immediately underneath it, and objects at a distance only slightly, the Jandus rays are better distributed over distant objects. Fig. 5 shows the amount of illumination on the ground at different distances. Assuming the lamps to be placed at a height of 20 ft., the ordinary arc lamp produces a prodigious illumination up to 20 ft. or thereabout, but then it rapidly falls off. At 34 ft. it is less than the light of the Jandus, and then it dies away almost to nothing. The Jandus, on the contrary, starts low, owing to the partial shadow of the lower carbon. As soon as we get out of the shadow of the corner of the lower carbon the light increases, and then, owing to the nearly horizontal direction of its maximum, it diffuses its light very equally, and, as you see, it illuminates objects at 140 ft. quite as much as the ordinary arc does at half that distance.

The advantages presented by the Jandus lamp may be summed up as follows:

It will burn on the public mains which have usually a voltage of about 110 without any accessories whatever.

The ordinary arc lamps must either be placed in series or must be furnished with a comparatively high resistance, so as to reduce the voltage to about 40. This means conversion of a good deal of electricity into heat which does nothing but keep the wire of the resistance warm.

The lamp is very economical, the consumption of carbon being insignificant.

The distribution of light is very equable, far more so than in the case of the ordinary arc lamp.

The construction of the lamp is extremely robust. There is no clockwork or delicate mechanism. Probably it might fall from a considerable height without sustaining any other injury than the smashing of the glass.

It is eminently suited for illumination of chemical and other works. It is an essential part of the construction of the lamp that it should be practically airtight. The working parts, therefore, would not be liable to be injured by gases or dust flying about in the factory.

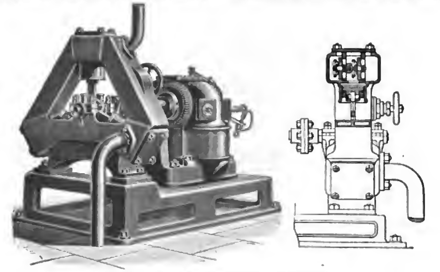
HIGH SPEED ELECTRIC MULTIPLE PUMP.

THE multiple pump represented in the accompanying engravings is of a new type, particularly adapted for use in country houses lighted by electricity. It is absolutely noiseless in its operation, and is capable, not only of being used for raising water to the reservoirs that supply the piping, but may also be provided with an arrangement to permit of accelerating the speed so as to increase the discharge at a high pressure in case of fire.

As may be seen, three pump chambers are arranged symmetrically with respect to the central shaft, which, ordinarily, is coupled directly with the electric motor. These three pump chambers, as well as the valve boxes and the channels for the circulation of water, are cast in a single piece with the triangular frame. Their diameter is relatively great with respect to stroke, which is short. It is thus possible to cause the pistons to operate at a high speed. The pump figured makes 700 revolutions a minute.

The clacks, which are of India rubber, are of special form—one that has already been adopted by the firm for its fire engines. They uncover a wide aperture with a relatively small ascent. In order to facilitate the starting of the electric motor, there is placed between the force and suction channels formed in the frame a by-pass valve cock, through the opening of which the charge upon the motor is rendered very feeble, so that it may be set in motion without giving rise to sparks.

These pumps are constructed in two series, one of which comprises those that are capable of running at two speeds for water and fire service and the other



HIGH SPEED ELECTRIC MULTIPLE PUMP.

those that run at a speed not exceeding 300 revolutions. The following are a few data in regard to these types:

FIRST SERIES.

Water per minute at 300 revolutions,	45, 68, 118, 180
" " " " 600 "	127, 180, 318, 530

SECOND SERIES.

Water per minute at 300 revolutions,	136, 200, 340, 545

The two small models of each of these series are constructed entirely of gun metal, except the frame, which is of cast iron. It is unnecessary to say that any sort of transmission may be used with these pumps, which, aside from the advantage that they possess of operating noiselessly, are remarkable for the constancy of their discharge and the small amount of space that they occupy.—Revue Industrielle.

AN ELECTRIC BAND SAW.

NOWADAYS, when it is a question of machines of a certain power, and that have to produce a large amount of work, an endeavor is made to run them electrically. We have already mentioned a large number of installations of machine tools of this kind, such as windlasses, cranes, lathes, drilling machines, etc., and now purpose making known a horizontal band saw driven electrically, and manufactured by the Société des Machines d'Oerlikon, in Switzerland.

This new machine consists of a bottom frame upon which rest rails and cross pieces designed to hold in position the trunk of the tree to be cut. By reason of the stability of the parts, boards of an absolutely equal thickness are obtained. The two pulleys that carry the blade of the saw are seen in front. Upon one of these pulleys, the one to the right, is placed a 16 h. p. electric motor. These two pulleys, along with the blade of the saw, can be easily raised by the simple motion of a lever and be lowered by means of a hand wheel, according to the thickness that it is desired to give the boards. In front of the apparatus, to the left, may be seen the interrupters. The velocity of the saw reaches about 38 meters a second.

The saw has likewise to move forward with great speed in advancing into the wood. The minimum value of such speed is 11 meters a minute. This motion is obtained through a 6 h. p. electric motor. This saw is capable of performing a large amount of work. In fact, it is easy to place a series of trees in its track so as to have it cut them in passing.

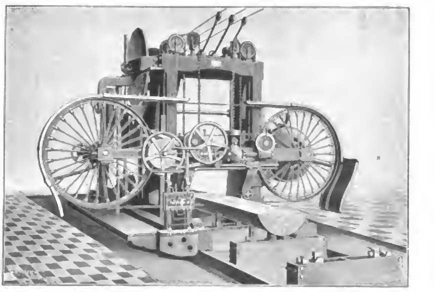
This machine tool has already been utilized in several installations, where it has rendered great services in doing the work of several laborers in a day.—La Nature.

THE USE OF TELEPHONES BY ROYALTY.

AN unaccredited item in one of the daily papers gives the following information, which is alleged to be correct, about the use of the telephone by the "crowned heads of Europe."

Now that Queen Victoria has at length permitted the installation of the telephone at Windsor Castle, Osborne House, Balmoral and Buckingham Palace, there is not a sovereign in Europe who does not utilize this instrument for communicating royal and imperial wishes, as well as commands to subjects and officials. Even the Pope, who has decided that, while a confession may be heard over the telephone, the priest cannot use the wire for the purpose of granting absolution, has had a receiver installed in his private apartments by means of which he often communicates with the Propaganda Fide, which is situated on the other side of the Tiber and at a considerable distance from the Vatican. It is generally his valet, Centra, who does talking over the wire for him, but he occasionally speaks over it himself, and only the other day, when a Jesuit priest was taken suddenly ill during a private audience, the Pope rushed to the little red lined booth and personally called up the Jesuit college, says an exchange.

King Leopold is enabled by means of the telephone



AN ELECTRIC BAND SAW.

to communicate with his ministers at Brussels without leaving his palace at Laeken or his marine residence at Ostend. When, a year ago, the little King of Spain was prostrated with the measles, and secluded at one end of the huge palace at Madrid, the Queen Regent was able to hold intercourse with him, located in a distant wing of the edifice, not only daily, but almost hourly, over the wire.

Queen Victoria, however, is so ultraconservative that it is most difficult to get her consent to any modern innovation, and it was only two years ago she permitted the installation of electric light in the state apartments of Windsor. Previously electricity, as well as gas, had been uncompromisingly barred from her private apartment. Yet it is almost impossible to exaggerate the importance of thus placing the various residences of the Queen in telephonic communication with London, as far as the transmission of official business is concerned.

Until now, whenever the Queen was desirous of consulting one of her constitutional advisers upon any point or when any cabinet minister had some matter of urgency to impart to Her Majesty, the unfortunate dignitary had to travel all the way from Windsor to Balmoral—a twenty-four hours' journey—or to Osborne, which entailed a sea trip across the stormy Solent, very often only for the sake of ten minutes' talk with the sovereign. Then, too, Lord Salisbury and even Mr. Chamberlain, both of them busy men, have had to spend a good deal of their time explaining matters to the Queen in writing.

In the same proportion that the Queen is old-fashioned in her views, in her surroundings, in her manner, and in her appearance, so is the Prince of Wales up-to-date. Marlborough House and Sandringham are fitted up with telephones and electric lights, in the most approved style. Should the prince survive his mother, his advent to the throne is likely to be marked by all sorts of innovations, which will have the effect of simplifying the present intricate manner of conducting the business of state.

In this respect he resembles his nephew, Emperor William II. of Germany, whose predilection for the telephone is a source of disgust to the various government officials at Berlin. There are instruments in his library and working room.

Although it may flatter the pride of the telephone people at Berlin to have the Emperor among the subscribers of the system, yet he gives them far more trouble than any other subscriber. For when he telephones to any of the government departments, the operators at the central office are under the strictest orders to abstain from listening to the conversation.

THE TESTING OF INDIA RUBBER GOODS.

WE have on more than one occasion been approached by buyers of India rubber goods with queries as to some method of ascertaining the quality, even approximately, of their purchases. Something besides chemical analysis is wanted, they say, as such analyses are not only apt to be expensive, but in many cases they do not indicate the presence of any latent evil, such as errors in mixing the materials or in vulcanization. Such faulty workmanship is apt, when the goods are in use, to show itself in an undesirable way, and consequently to lead to passages of arms between buyer and seller, a condition of things to be avoided in the interests of both parties. It is the wholesale buyer who more often finds himself in difficulties in this way, because, although he can generally by strong representation get the goods complained of replaced by the manufacturer, yet such replacement does not obliterate the effects of the evil, as loss of trade resulting from a bad name is not regained all at once. Another great drawback to chemical analysis is that the goods have to be cut up, or, at any rate, cut into, at some point or other to obtain material for the analyst to work upon, and in many cases it means a serious loss to do this. Again, the cutting up of one article of comparatively small value does not conclusively show that the figures obtained from its analysis apply to the whole delivery of which it is a unit, such is the variation that is so commonly found in deliveries of rubber goods. Thus chemical analysis, on the whole, seems out of the question, and it therefore remains to be seen how far physical tests can be adapted so as to give a fair criterion of the quality of the goods and of their suitability for the purposes for which they are intended, while at the same time no damage is done to the articles by the test so as to unfit them for sale. To mention some specific cases, it may or may not be matter of common knowledge that the majority of our leading railway companies submit all deliveries of carriage and wagon buffers to severe mechanical tests, and such as fail to reach a certain standard are rejected. It should be mentioned that such tests are only insisted on by those companies who pay a fair price, and expect to get sound rubber.

At the present time there are great variations in the prices paid by railway companies for goods intended for the same purpose, three times as much being paid in some cases as in others. We doubt the policy of buying cheap and nasty mechanical rubber, but in the light of what has occurred in other branches of the rubber trade, it is gratifying to find that the railway companies who buy such goods do not expressly stipulate that they shall stand the tests usually applied to the best quality. This testing of buffers on a large scale of course takes time, and involves, in addition, the purchase of rather expensive machinery; but there is no doubt that it pays the buyer. Without going into great detail, it may be said that the buffer testing machine is on the principle of the ore stamp, five or six hammers being worked by a cranked axle, and striking blows on as many buffers. The superficial dimensions of the buffer springs are carefully measured before and after the test, which may consist of from 1,000 to 10,000 blows, and may last a whole day. A good buffer should measure the same after as before the test, though one of inferior quality, i. e., wanting in elasticity or badly vulcanized, will be found to have sustained a permanent set after the test. It will be seen at once that this test is of more value than any chemical one would be, and it puts the rubber manufacturer on his mettle, as it is no easy task to get such an equality of vulcanization as is required to conform to the standard of this test. We have known of cases where half a delivery has been returned as unsuitable, though to the best of the rubber manufacturer's knowledge the material and the method of manufacture was similar throughout. We rather suspect that variations occur in the rubber which are not to be detected unless by some such severe test as the one under notice, and which could hardly be discovered in the unvulcanized rubber, though this is a technical matter which does not directly concern us at the present moment. It is necessary to add, however, that, whether owing to this inequality in the elasticity or lasting power of rubber buffers, or to other causes, there seems to be a decided revulsion of feeling in favor of steel springs for rolling stock at the present time, and it behooves the rubber manufacturers to look to their guns unless they wish to lose a considerable business. We append here some figures obtained by a railway company from a delivery of buffers all supposed to be of equal quality, and they show decidedly that some variation either in the quality of the rubber or in the method of manufacture has occurred:

	Loss after Plates. Per cent.	Loss after 10,000 Machine Blows. Per cent.
1	nil	50
2	"	39
3	"	19
4	"	25
5	"	10
1	2	48
2	8	43
3	17	36
4	7	45

The loss after plates, it should be said, refers to the permanent decrease in thickness noticed after the buffers have been screwed up under pressure for a length of time between iron plates, and the percentage of loss refers to the decrease in lifting power or elasticity. For example, a buffer which will lift a weight of 6 tons before undergoing the machine blows and only 3 tons afterward shows a loss of 50 per cent. It is rather exceptional for a delivery of buffers to show such great variations as are given in the table, but the figures show the value of the test from the railway engineer's point of view. Other railway goods, such as vacuum diaphragms, hot water hose, etc., cannot be so easily tested, though a system of testing high pressure steam tubing by attaching two or three lengths to steam jets, and comparing their behavior under pressure, has been adopted with good results, as indicating the temperature and pressure the hose is capable of standing without injury. Leaving the railway companies, we may glance at some points in the specifications sent out by the Admiralty, who are large buyers of rubber goods, and for whose contracts there is considerable competition. The rubber has to be supplied in the form of vulcanized sheets, and it is cut into valves, washers, etc., as required at the various dockyards. Three qualities of rubber are bought, and the exact amount of rubber, mineral and sulphur they are to contain is specified, any variation from the figures given rendering the contractor liable to have the goods thrown back on his hands, a contingency which it is unnecessary to say involves him in considerable loss. The testing employed seems to be almost entirely chemical, and the strictness with which the authorities visit any variation from the limits of sulphur laid down in the specification is carried to a degree which we venture to say is hardly warranted. The idea of a low limit of sulphur is, we suppose, that the goods are less liable to deteriorate when in use by reason of oxidation of uncombined sulphur; but it must not be overlooked that a low content of sulphur necessitates a prolonged vulcanization, and it is extremely doubtful, to say the least of it, whether this prolonged heating is better for the rubber than would be the presence of say an extra one-half per cent. of sulphur, which would lend to shorten the time of vulcanizing.

Some few years ago Lieutenant Vladimiroff, of the Russian navy, made a series of experiments to establish the testing of rubber goods on a sound and satisfactory basis, the following being the main conclusions at which he arrived. It will be seen that the tests advocated are physical ones, as he came to the conclusion that chemical testing gave no reliable results.

1. India rubber should not give the slightest sign of superficial cracks on being bent to an angle of 180° after five hours' exposure in a closed air bath to a temperature of 125° C. The test pieces should be about 6 centimeters thick.

2. Rubber containing not more than 50 per cent, by weight of metallic oxides should stretch to five times its length without breaking.

3. Pure caoutchouc free from all foreign matter, except the sulphur necessary for its vulcanization, should stretch seven times its length without breaking.

4. The extension measured immediately after rupture should not exceed 12 per cent. of the original length of the test piece. The test pieces should be from 3 to 12 millimeters wide and not more than 6 millimeters thick and 8 centimeters long.

5. The percentage of ash gives a certain indication of the degree of softness, and may form a basis for the choice between different qualities for certain purposes.

Any excess of sulphur over that required for vulcanization should be removed at the works, and should not appear on the surface of any object.

Now these tests on the whole seem very well calculated to give useful indication to engineers as to the quality of the goods they are buying, only we would interpolate here the remark that unless a good price is paid for the rubber, it is no use submitting it to such physical tests as these. India rubber substitutes made from oil, and "recovered rubbers," i. e., old rubber worked up again with oil, have nothing like the elasticity appertaining to new sound rubber, and they are quite incapable of standing the elongation or heat tests mentioned. The concluding remark of the lieutenant is somewhat naive, and though no doubt it expresses a desirable consummation, we may perhaps be permitted to ask how it is to be effected. No doubt the excess of sulphur over and above that required for vulcanization should be removed, but how is it to be done? In the case of thin goods, consisting of rubber and sulphur only, it is possible and, indeed, is the regular practice, to remove the excess of sulphur by boiling in a solution of caustic soda, but this could not be done in the case of valves or buffers over an inch thick. Of course the alternative to this is the English Admiralty low limit of sulphur, but, as we have already said, we are not particularly enamored of this, and do not feel inclined to recommend its more general inclusion in rubber specifications.

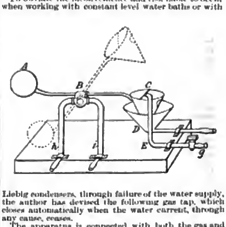
The specific gravity of a rubber compound, or what comes to the same thing, the number of cubic inches to the pound, is very generally taken by buyers as a correct index of the value, though in reality such is often very far from being the case. In the rubber works the qualities of the rubber made vary from floating, the best quality, to densities corresponding to 11 or 12 cubic inches to the pound, the latter densities being in demand nowadays by many consumers with whom price appears to be the main consideration. It will be obvious that such densities as these can only be obtained by utilizing to the utmost the quality that rubber exhibits of taking up a large bulk of added matters.

In Lancashire a common test of mechanical rubber is to throw it into the millpond to ascertain its floating power or otherwise. Of course it is all right as discriminating between a floating and a compounded rubber, but the mere fact of a rubber floating does not show that it is necessarily of a good or elastic quality, because it must be remembered that there may be a large amount of extraneous organic matters present in the form of oil substitutes which are of practically the same density as rubber. By such a test a compound containing a considerable quantity of substitute is found superior to one consisting of the best rubber and 20 per cent. of zinc oxide, a conclusion which would not by any means be borne out in practice. We therefore hold out a word of warning to buyers of rubber goods not to set too much store by this gravity test, as it may very often afford an incorrect criterion of value, though at the same time it is difficult to suggest an alternative test of equal simplicity, or one that does so little damage to the goods. It is, of course, apparent that rubber containing 10 or 70 per cent. of mineral will sink equally in water, and it is useful to extend the test by employing solutions of common salt or chloride of calcium which a rubber of approved density will float in, and samples can be compared with this as a standard at any time. Space prevents our going further into this matter of rubber testing, and we shall conclude with the observation that on the whole what the Russian authority says about the inadequacy of chemical analysis is well founded, and it behooves engineers to work out special mechanical tests easy of application which may serve to convince them that what they are buying is—to use a borrowed expression—of the nature, substance and quality demanded.—Engineering.

AUTOMATIC GAS TAP.

By H. MICHAELIS.

To obviate the inconvenience and risk liable to occur when working with constant level water baths or with



Liebig condensers, through failure of the water supply, the author has devised the following gas tap, which closes automatically when the water current, through any cause, ceases.

The apparatus is connected with both the gas and water supply, and its construction is shown in the accompanying figure.

The gas flows through the tubes, h, i, so long as the lever attached to the tap, B, remains horizontal. This lever carries at one end a weight, A, and at the other a funnel, C. The tube, E, is connected with the water supply, the tap being at g, and through it water flows into the funnel, C, running away partly through a small opening at the apex of the funnel and partly through an overflow opening somewhat below the funnel rim, into the larger funnel, D. So long as the funnel, C, is filled with water—i. e., so long as the water feed continues—it balances the equal weight, A, and the tap remains open. Should the water supply cease, the water in C runs gradually away through the small apical opening, and the weight, A, then bears the lever down until it takes up the position shown by the dotted lines, in which the tap is closed.

The water supply to the funnel, C, may be the overflow from the water bath or condenser. The water must, naturally, be fed into C more quickly than the lower opening in the funnel will allow it to flow into D.

There is also a small hook, not shown in the figure, to hold the lever horizontal, should it be desired to use the burner alone and without the water supply.—From the Berichte in the Journal of the Society of Chemical Industry.

Some tests recently made on molybdenum steel by Prof. W. Von Lipin, of St. Petersburg, show that molybdenum steel resembles wolframium steel in a general way, although it is less affected by annealing and tempering. Annealing makes it softer than wolframium steel; high heating, on the other hand, makes it harder than the latter. This steel can stand treatment in the fire as well as tempering better than wolframium steel, and shows no fissures where wolframium steel very often does. This may be the cause for the numerous attempts to substitute molybdenum for wolframium, and especially chromo-wolframium steel.

ENGINEERING NOTES.

The traffic on the London Metropolitan and Metropolitan District railways for the first half of 1897 amounted to 69,260,675 passengers, says Engineering News. At this rate the total traffic for 1897 would be 138,521,350. In 1896 the actual number of passengers carried was 131,131,305, as compared with 121,063,903 in 1886 and 76,388,117 in 1876. The Metropolitan Railway is a little over 60 miles long, and the Metropolitan District operates about 14¼ miles. The length of line worked by the engines of the first named company is 89½ miles and that of the second is about 36 miles. During the first half of 1897 the aggregate train mileage of the Metropolitan was 1,441,152 miles and that of the Metropolitan District was 765,420 miles. The one company on July 1, 1897, owned 80 locomotives, 400 passenger cars and 242 freight trucks, and the other company owned 54 locomotives, 371 passenger cars and 35 freight cars. The capital expended by the Metropolitan Railway to July 1, 1897, was $61,328,765, while the Metropolitan District had expended to the same time $28,081,065. The net revenue from the first named line for the first half of 1897 was $1,174,290 and that of the Metropolitan District was $627,740.

A curious accident took place in France lately, says The American Architect. On the third of July, an inundation of the River Adour carried away a stone railway bridge at Tarbes. It happens that General Mareille, of the engineer corps of the French army, has devised a form of steel bridge for military purposes, which can be transported in sections, and quickly erected in place; and the railway company applied to the military authorities for a bridge on this system, to serve temporarily, until the stone bridge could be rebuilt. Several of the Mareille bridges have already been successfully used, and sections are kept ready at the army stores, so that on July 17, two weeks after the accident, the new bridge had the rails laid over it, and was ready for testing. The test was made by running a testing train, consisting of two locomotives, with their tenders, and two loaded freight cars, on the bridge. Hardly had the train advanced fairly upon the bridge, running very slowly, when the box girder, of which the bridge substantially consisted, began to twist in the middle, and gave way, throwing the train into the river. Several men on the train were injured, but, fortunately, no one was killed.

There is a strong tendency among bicycle makers in pandering to the public taste for lightness of parts to reduce the size of the sprocket wheel on the rear axle. That this is a mistake is proved by an experiment recently made to determine the comparative efficiency of sprockets of different sizes. To carry out the experiment the bicycle was inverted, and the frame securely attached to the floor. A thin steel band had one end attached to the tire, and the other end carrying a weight which was raised by the band being wound upon the tire, a second weight being hung from a scale pan attached to the pedal, whence the efficiency of the portion of the mechanism transmitting the power could be calculated. A long series of readings were taken with the same large sprocket and with seven, eight and nine toothed sprockets on the rear, and with pedal weights varying from 2 lb. to 30 lb. The average efficiencies in each case were as follows: 7 tooth, 89·9; 8 tooth, 91·5; 9 tooth, 93·4. This shows the 8 tooth to have 98·0 per cent. of the efficiency of the 9 tooth and the 7 tooth to have 96 per cent. of the efficiency of the 9 tooth sprocket, other conditions being equal. The result proves that there is less chain pressure upon the teeth of the larger wheels, and hence less wear.

The friction of bicycle chains is being investigated in the engineering laboratories of Sibley College, Cornell University, under the direction of Prof. R. C. Carpenter, says Engineering News. The question of chainless gearing has also received some attention. The results of the tests so far made are unfavorable to all forms of wheels driven by other means than the usual chain. Prof. Carpenter says: "Our investigations are not entirely completed at the present time, but it seems safe to announce that all the tests indicate that no form of gearing can possibly equal the best chain for efficiency and durability." As a result of tests of chains which had been in actual and severe use, it was found that friction varied from 2 to 5 per cent., depending upon the construction and previous use. The highest friction found was 10 per cent., in the case of an old chain which did not fit the sprocket. The friction of a complete wheel was tested under working conditions in several instances and found to vary from 5 to 40 per cent. of the power applied. For high grade wheels this value ranged between 5 and 8 per cent. In all the tests of bevel gears and geared bicycles the chain gear was found more efficient than the other forms. Another feature adding to the success of the chain in competition with chainless wheels is that the friction remains practically constant at all loads, while with the geared wheel the friction is greatest when the load is greatest.

Milwaukee's use of its fire boats for fighting fire at a distance from the river front is attracting attention in other cities with navigable waters. Cleveland, Detroit and Buffalo have adopted the system, and Boston is preparing to do something with it. In Milwaukee the idea was born of necessity, the first suggestion being for a pipe line from the river to an isolated manufactory in a section where the water mains had not penetrated. The pipe was laid, and the first test with a fire boat at the river end showed a complete success. Since then lines have been laid to cover a great part of the business district of the city. They extend in some instances even as far as 3,000 feet from the river on either side, and have been proved to be effective even with an elevation of 96 feet, and the consequent large back pressure. The chief of the fire department says that a fire boat at the end of a pipe line is worth from three to six engines, according to the length of the line. Therefore, by the extension of the lines at a comparatively small cost, the city has been saved the expense of several engines, to say nothing of the engine houses and the keeping up of companies. The piping costs but little more than the same length of hose, and when laid is practically indestructible. In time at least one-half of Milwaukee will be protected in this manner—a protection more efficient than that provided by fire engines and obtained, moreover, at a minimum of cost.—New York Evening Post.

ELECTRICAL NOTES.

The material most commonly used for the cores of electromagnets is soft iron, on account of its high permeability. But soft Martin steel is often quite as effective and is more easily obtained. It may be used wherever a rapid change of magnetization is not essential. A comparison, undertaken by A. Abt, between two exactly similar horseshoe cores weighing 47 kilogrammes of soft steel and soft iron respectively, gave 0·98 to 1·04 for the ratio of the permeabilities of the former to the latter, and 1·2 to 1·3 as the ratio of the permanent magnetisms. This places soft steel very close to soft iron in magnetic behavior. Cores of steel have the additional advantage over iron of greater tenacity.—Abt, Wied. Ann., No. 8, 1897.

The Plunger, a submarine torpedo boat of the Holland type, designed for the United States navy, was successfully launched at the yards of the Columbia Iron Works, Baltimore, on August 7. The boat is cigar-shaped, eighty-five feet in length and eleven feet five inches in diameter. When floating light, it had a displacement of one hundred and fifty-five tons, and when down to the load line, one hundred and sixty-seven tons. A steam plant is provided to operate twin screws when afloat or awash, and a seventy horse power motor, furnished with current from forty-eight storage batteries, will operate the vessel when submerged. The steam power, electric dynamo and storage cells are so arranged as to be readily reversed, thus making it possible to recharge the cells from the power plant on the boat. The electric power may also be connected to the propeller shaft placed in the axis of the boat, in addition to the connection with the main propeller shaft. The motor may thus operate a special propeller in addition to driving the main shaft independently of the steam engines.

The Street Railway Journal says: "We notice that the Electrical Review, of London, takes exception to the statement of President Clark, of the New York, New Haven & Hartford Railroad, that cars have been operated for hours over sections of his line when both the third rail and service rails were covered with water. The Review evidently thinks that such a thing is impossible and 'a piece of exaggeration that any tyro would detect.' It is true, nevertheless, that such things have happened and can happen, and, in fact, may be expected to happen under such conditions as are found at Nantasket Beach, for it is a fact demonstrated repeatedly in conduit and third rail work that the resistance of rain water or even of water which is by no means chemically pure is sufficiently great to prevent a leakage approaching a short circuit on a line with only five hundred volts pressure. Those who have tested railway plants with water rheostats can easily understand this, knowing the difficulty of forcing a large volume of current through a body of water, unless the plates are placed quite close together; and we may add for the benefit of our doubting contemporary that the recent heavy rains in Connecticut flooded the tracks of the Hartford-Berlin third rail electric road without interfering with operation."

A portable motor and drill, with magnet, for use in iron and steel plants, where heavy castings and forged pieces must be transferred from one department of an establishment to another, is described by Dr. Louis Bell in The Engineering Magazine. The motor is provided with a worm driven drill, together with a universal mounting of four adjustable feet. When placed fairly upon a ship's plate or other mass of iron, these drills have an adhesive force of nearly half a ton each. The drill can be adjusted and clamped by the simple turning of a key, and it will bore holes up to an inch in diameter as fast as it can be safely worked. The whole affair is of only about two hundred pounds weight. Another convenient application of this principle is reported as in use at the works of the Illinois Steel Company. In the rolling of boiler plates, the resulting sheets, twenty or more feet long and weighing from a quarter to half a ton, are, of course, difficult to handle, and, when to be moved, are objects very difficult or inconvenient to sling. To meet this difficulty, a pair of powerful electromagnets were rigged up and attached to the traveling crane, so that all that is now required is to drop these magnets down upon one of the long plates, which is thus held at two convenient points, and to send it rapidly down the room, dropping it into place without a jar.

The Canadian government has submitted formal proposals to this government to establish communication with the Klondike region in Alaska by the construction of a telegraph line from the head of winter navigation on the Lynn Canal to the center of the Klondike region. The proposals have been taken under advisement, says the Electrical World. They have been approved by the British Principal Secretary of State for Foreign Affairs, and were forwarded by the Governor-General of Canada through the British Embassy to the State Department and referred to the Interior Department. The papers are locked up pending consideration. The proposals, while reserving the right of either country pending the settlement of the international boundary line between the United States and Canada, south of Mount St. Elias, urged the expediency of establishing a permanent route giving access to the interior at all seasons of the year. The most feasible route, according to the Canadian authorities, would be to start from the head of the navigation in the winter on the Lynn Canal (the body of water running from Juneau up beyond Dyea and Chilkat), forming part of the present overland route, crossing the mountains by White Pass or by any other pass which may seem more accessible, and proceed northward to Fort Selkirk and thence to Klondike. The Canadian government asserts its readiness to undertake to open communication by constructing a telegraph line from the head of winter navigation on the Lynn Canal, traversing a distance of eighty miles, across the summit of the mountain range to a convenient point northeast of the mountain range, from which a trail can be followed to Fort Selkirk and Klondike. The government also signifies its intention, in case the propositions are adopted, to erect suitable places for shelter at periods from forty to fifty miles along the line, and to keep up dog trains during the months of winter for the conveyance of the mails to and from the interior.

MISCELLANEOUS NOTES.

The old sumptuary laws of the middle ages are called to mind, says The Iron Age, by a singular decree which has recently been issued by the Bulgarian Ministry of Agriculture and Commerce, by virtue of which all the officials and functionaries of the state, of the towns and of the communes in that country, and even deputies when in session, are compelled to wear clothes and boots made in the country, of stuff or leather also produced in the country, under penalty of fine or other punishment. The cloth and leather in the piece must bear a certain mark, which mark must also be found in the made up article. Where the Bulgarian officials have ordered clothes and boots, they are obliged to retain an invoice as a proof, and when buying new clothes, must notify the official in control.

The introduction of a new oarlock for boats is recorded by the Chicago Tribune as involving an additional extension of the ball bearing system in minimizing friction. As described, the rowlocks in this case are of brass, with three point ball bearing, casehardened steel working parts; they are furnished in either polished brass or nickel plated, as may be desired. These materials will not bend or spread, and so the oars will move in them always the same, and thus there can be no liability to uneven rowing on account of the locks being of different shapes and angles, as is not infrequently the case with compositions of a softer character. The statement is made that this ball bearing rowlock affords an ease in rowing which is most remarkable.

The French manufacturers of asbestos goods are supplied from four sources, says the Engineering and Mining Journal: 1. Canada, whence the asbestos is white, silky, very unctuous, having supple fibers from 5 to 25 mm. in length; of all varieties it is that which spins the most easily. 2. Siberia, whence the mineral is yellowish, some species from the straw yellow. The fiber is less flexible than the Canadian, more woody and dry, but stronger. Their length is about the same as the Canadian, but large masses of long fiber mineral are rarer. 3. The Cape of Good Hope asbestos has a characteristic blue color. It comes in larger pieces than either the Canadian or Russian, and their fiber is generally longer and stronger. In spinning or other manipulation, however, it is difficult to handle them, a good deal of the fiber being reduced to powder. 4. In Italy there are different kinds of asbestos, but generally they are little adapted to spinning. There are some long silky fibers of little resistance employed for gas furnaces, and others which are very short and fit only to make heat-retaining coverings.

For ages the English and French controlled the manufacture of hair pins, and it is only within the last twenty years that the goods have been produced in other countries to any extent. The machinery used is of a delicate and intricate character, as the price at which the pins are sold necessitates the cheapest and most rapid process, which can only be secured by automatic machines. The wire is made expressly for the purpose and put up in large coils, which are placed in a clamp and so carried to the machine while being straightened. This machine cuts, bends, and by a delicate instantaneous process sharpens the point. Running at full speed, it will turn out 120 hair pins every minute. To economize, it is necessary to keep the engine going day and night. The difficult part of the work is in the enameling, which is done by dipping the pins in a preparation and baking in an oven. It is here that the most constant and careful attention is required, as the pins must be absolutely smooth and the enamel have a perfect polish. The slightest particle of dust causes imperfections and roughness.—Pearson's Weekly.

The British Liquor Licensing Laws Commission has just issued a report that contains some interesting information about temperance drinks, a subject that might properly interest the United States Treasury Department, not to say American temperance societies. What is called "herb beer" was found to contain 11 per cent. alcohol, a warranted "blue ribbon" drink contained 8 per cent., "parsnip beer" contained 14 per cent., which is more than the beer usually sold in the saloons contains, and even more than that was found in "horehound beer," "bicycling tonic" and "temperance beer." Ginger beer, a favorite temperance beverage, was found to contain from 5¼ to 8¼ per cent. of proof spirit. "And," remarks a British newspaper, in commenting upon the discoveries of the commissioners, "not merely the drinks, but the sweets which more or less innocent children are in the habit of consuming in larger quantities than is good for them, are, alas! not free from alcohol." It is just possible that a great many total abstainers will not thank us for mentioning the alcoholism of drinks hitherto believed to be free from that article. In England the laws allow a 2 per cent. alcoholic beer to be sold without a license.

Almost all the bristles used in this country in the manufacture of brushes are imported, and notwithstanding the increased production of pork in this country, the supply of American bristles is now even smaller than it formerly was. Hogs are fattened and killed young in this country, and with the constant and widespread improvement of the breeds here, the hogs have run less to bristles. Some extensive packers collect bristles, but the American supply is probably less than 1 per cent of the consumption. The longest American bristles are about four and a half inches in length. Imported bristles come from various parts of Russia, but most largely from Poland and North Germany. Some finer soft bristles come from France. The bulk of the supply comes from cold countries, where the hogs are well protected by thick coats, and many of the bristles are those of wild hogs. The hogs shed their coats as many other animals do, and there are men who gather the bristles of wild hogs, knowing their haunts and where the bristles are to be found. Other bristles are collected in the usual manner when the hogs are killed. The bristles are subjected to various processes of curing and preparation before they become commercial bristles and ready for the market. Imported bristles range from three and a half to seven and a half inches in length. Various vegetable fibers are now used extensively in the manufacture of cheaper brushes, but for many uses bristles are indispensable and their importation continues steady.

THE NEW CATHEDRAL IN BERLIN, GERMANY.

SINCE the time of Frederick William IV. of Prussia it has been the desire of the monarchs residing in Berlin to erect a new cathedral for their use on the site of the old church built in the reign of Frederick the Great. On two occasions plans had been completely drawn up, but neither of them came to execution. Now, at last, two and a half million dollars have been granted toward the realization of the present Emperor's desire to accomplish what his fathers were prevented from doing. Professor J. C. Raschdorff and his son, Professor Otto Raschdorff, presented such a plan for the cathedral as was in proportion to the sum granted, and on June 17, 1894, the foundation stone was laid with great ceremony.

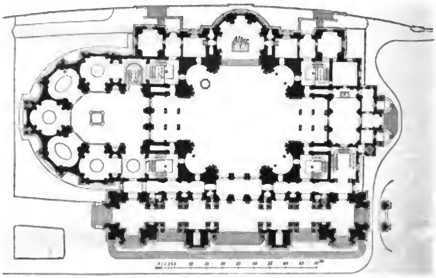
Our illustration, which we take from Ueber Land und Meer, shows the cathedral as it will appear when completed, looked at from the west, on the main façade. From the east façade there are steps leading down to the Spree River. To the royal castle, which lies on the right, the Kaiser Wilhelm's Brücke (Emperor William's bridge) and a street of the same name lead past fine cupola crowned houses, which also can be discerned on our illustration. On the left and right of the Lustgarten (the square in front of the west façade) stand the new museum and the National Gallery. Surrounded by grand buildings on all sides, the new cathedral will stand on one of the finest squares of the world.

We also reproduce from the same source as our illustration an elevation of the church. The longitudinal axis of this is 416 feet in length. In the center the main hall is built in form of a cross, of which the altar occupies the east arm; to the north arm (on the left) is attached the monumental chapel, itself surrounded by five elliptic chapels. Opposite, on the south, lies the chapel for marriage and baptism ceremonies. In the west a corridor runs parallel to the length of the building, connecting the various parts of the church, and leading at either end to a flight of stairs. In front of this corridor is the entrance hall, supported on a number of pillars, and opening with five doors on the steps leading to the Lustgarten.

The baptismal chapel will accommodate some 100 people; it is surmounted by a massive sandstone vaulting, and has a gallery for the choir. The main church has about 2,000 seats. The chancel is placed in the recess on the right of the altar, while the one laterally opposite contains the royal box. The north arm of the cross formed by this central hall is occupied by the organ and choir. High above the hall, 244 feet from the floor, a cupola 104 feet wide sheds its many colored light into the cathedral. A whole church with a good spire could be placed within this central hall. In the walls of the cylindrical structure which supports the cupola there are eight windows, each 32 feet high, which add their light to that given by the cupola. The walls are richly decorated with plastic ornaments. The monumental chapel is intended for the statues and memorials of the Hohenzollerns. The actual coffins are laid below in the vaults which extend under the church. The chapel is lit up by a large skylight in the vaulting, which is 61 feet wide. The walls of the small chapels around are of the most beautiful Mexican onyx, the columns are of red marble. From without the several halls can be distinguished by the appropriate shape of the exterior. Thus the cupola of the main hall rises high above the rest of the building, while on the left and right the baptismal and monumental chapels respectively raise their less pretentious cupolas. The central cupola is surrounded by four towers situated at the corners of the building, of which the front two are 210 feet high and hold the bells.

The entrance to the church is formed by a great arch, with fine columns on either side, over which is placed in a niche a figure of Christ, wrought in bronze, and over 16 feet high. At the same height, on the façade, are figures of the twelve apostles, and at the foot of the two pairs of great columns are grouped the four evangelists and the four great prophets of the Old Testament.

The cathedral is distinguished by its beautiful proportions, its simple grandeur, the perfect distribution and harmony of its mass; all this and the oneness of the building prove it to be the work of no mean artist. To the present time the church is complete up to the cornice. The great cupola has progressed to where the dome begins to spring. The iron frame of this cupola will be put up this year, and it is hoped that in two more years, for the Emperor's birthday in 1900, the whole cathedral will be ready for consecration.



PLAN OF THE NEW CATHEDRAL AT BERLIN.

THE NEW CATHEDRAL AT BERLIN, GERMANY, AS COMPLETED.

NEW GOBELINS TAPESTRY FOR THE EXPOSITION OF 1900.

THE author of this pleasing composition has fully succeeded in giving it the artistic character of the last century, and under the fingers of the skillful artists of the Gobelins the wool will render still better than color the luminous, chatoyant effects of the costumes of the period.

M. Claude has been able to obtain marvelous effects for the general harmony of his work from the pretty fashions of 1792. How far we are here from the monotony of the present costumes, especially on the masculine side! Here, the mayor himself is graceful and showy, with his white powdered wig, his clothing of black taffeta and his scarf worn over the shoulder, and not around the waist. The secretary is clad in apple green silk, and thus introduces a very lively note into the symphony.

As for the bride, she is absolutely ravishing with her hat "à la bergère" crowning a reddish flaxen head of hair. Her frock is of a light rose color, ornamented with all the furbelows of the fashion of the day.

The groom also presents a very fine appearance with his light blue coat, his amaranth knee breeches and his white silk stockings. The guests very harmoniously encircle the principal group.

At the Gobelins there has been taken up the very rational and eminently decorative method followed by the majority of the skillful tapestry workers of the last three centuries.

The tapestries are surrounded by wide borders formed of most fanciful motifs—flowers and fruit, animals, arabesques, etc.

As the "Civil Marriage in 1793" is destined for the Salle des Mariages of the mayoralty house of Bordeaux, the arms of this illustrious city have been very cleverly introduced into the magnificent border.

The city of Bordeaux, as well known, bears the crescent in its coat of arms, not on account of Mussulman sympathies, but simply because of the form of its port. This is why three gracefully interlaced crescents figure at the four corners of the border, in addition to the coat of arms that occupies the center of the upper band.—Le Magasin Pittoresque.

CIVIL MARRIAGE IN 1793—A NEW GOBELINS TAPESTRY.

The first ship having triple expansion engines to enter the transatlantic trade was the Martello, built in 1884 for the Wilson Line by Earle's Shipbuilding Company, of Hull. This ship was 370 ft. long, 43 ft. beam and 28 ft. deep. She had engines with cylinders 35 in., 50 in., and 82 in. in diameter and 57 in. stroke, carried 150 lb. working pressure, indicated 2,400 horse power and made 12 knots on a consumption of 38 tons of coal per day.

IMPROVIDENT CIVILIZATION.*

A PLEA FOR THE APPLICATION OF SCIENTIFIC METHODS TO THE AMELIORATION OF SOCIO-ECONOMIC DEFECTS AND DISORDERS.

By RICHARD T. COLBURN.

IV. SPENDTHRIFT LUXURY.

TRAVELERS in the Swedish-Norwegian peninsula concur in opinion as to the high general average of thrift and contentment existing, in spite of the uncongenial climate, the paucity of manufactures for export, and the presence of an aristocracy and a considerable standing army. The extremes of riches and poverty are not so great. What a pity that this Scandinavian secret of contentment cannot be made available in our more fortunate lands! True, there is a large consumption of ardent spirits, but the humid climate may account for it, or diminish its worse effects. Then the ratio of illegitimate births is high, but this is not to be charged to moral laxity of the women so much as to restraint laid upon the marriage of the young men by army and church. No very complete explanation of this Utopian satisfaction is offered beyond a pervading high literary standard due to excellent public schools; to a general and steady industry on the part of the whole population, male and female, young and old; and the absence of pretentious and ostentatious displays of wealth. The latter may be due to an anxiety to escape the tax gatherer; but it is refreshing to find one instance where the more liberal education coexists with industry and contentment, which it is fashionable in some countries to regard as incompatible. The same thing is true of Holland, which, however, lays the world under tribute by its floral tubers and Spice Island colonies; but Dutch thrift has made her a solvent creditor nation, and in time of stress she has but to sell her investments to draw from others. Other examples might be cited, Switzerland for one. The lesson to be deduced is the same, that industry, thrift, frugality, are the cure for hard times, for international competition, and contribute to good morals and stability of social order and progress.

Living, or rather working in the commercial metropolis of the continent, where is landed eighty per cent. in value of the importations of fabricated wares, I am continually impressed with the prodigality of our expenditures for things which have little, or only a transient, value. The loss of money, great as it is, is only the smaller part of the injury. It is at least debatable whether it would not be true economy, after having paid for the goods, to throw them all overboard in midatlantic—not at all on behalf of encouragement of home manufacture of similar articles, but to be rid of the pestiferous example and influence. These foreign articles not only keep the nation poor, but also debauch the public taste and conscience, set up false standards of what we can afford, introduce a succession of absurd fashions, and convert what should be stalwart men and women into mere fops and imitators. New York makes its living—a large share of it—in handling these importations, and distributing them widespread over the continent; and the greater its trade of this sort, the more the country is ruined. Its press, of course, from interest, if not from conviction, advocates the greatest freedom of trade, especially of so-called "objects of art," whereon the profits are so large as to leave a wide margin for advertising purposes.*

Consider for one moment what we get: a collection of millinery, bric-a-brac and finery which sooner or later finds its way to the attic or the rubbish heap; then reflect what we part with: the most precious part of our inheritance and labor, the phosphatic and nitrate constituents of the soil which do not quickly reproduce themselves like the ice taken from a lake, but are rather like the marble taken from the quarry. Deforestation may be followed at long intervals by reforestation, perhaps after damage by droughts and floods; the draughts on the fisheries (but not it would seem of the seal fisheries) may be made good by stocking, or by a close season; not so the soil, which must be replenished, or it soon ceases to repay the labor of tillage. Subsoil plowing cannot go on forever and adds to cost. The same cereals and breadstuffs we sell, at bare cost of production, the railroads are compelled to transport at a rate equal only to the train expenses, leaving the burden of interest on cost of construction to be borne by local or domestic traffic. The freight on a barrel of flour from points 1,000 to 1,500 miles inland to Liverpool is but a trifle more than to cart the same across any single city, and much less than to convert it into bread. Indeed, dealers have exhibited in Chicago loaves made of Minneapolis flour, in Glasgow, of the same weight and cost as those produced at the lake port. It only remains to complete the reductio ad absurdum to reimport the Scotch bread in competition with the home-made article. This, however, is what we actually did for years with our cotton and wool fibers, sending them to Europe to be spun into thread and cloth, and would have continued to do so to this day if the arguments of the à priori economists could have prevailed. This is national improvidence; and its logical outcome is national dependence and national impoverishment.

By a provision of the Constitution, inserted at the instance of the more agricultural provinces, an export tax was forbidden to be levied. There has not been as yet much to regret in consequence; but one result is that any advantage which the United States may possess either in climate, soil, or beneath its soil, must be shared with other nations at the cost of extracting and transport. Our Canadian cousins are not so hampered, and are putting an export duty on logs and wood pulp. Russia and America have the great workable petroleum fields, without which the cost of illuminants would have been enhanced. How long these deposits will last is a matter of conjecture, and they are obviously more or less of a speculative investment. While free competition was possible, there was a general rush to empty them upon the glutted market at whatever the oil would bring. The State of Pennsylvania would have been justified in expropriating the entire territory and conserving the product for the benefit of another as well as the present generation. It might do so yet with advantage. The alternative was a combination of small owners into one great excusable monopoly. When this precious deposit is exhausted, we shall have the slender satisfaction of knowing we helped to light and warm the world at no profit to the owners, unless the upbuilding of one or two large estates is to be accounted a compensation. A like history is to follow our depleting reservoirs of natural gas. The same reasons apply pro tanto to the anthracite deposits in a very limited area; parts of five counties in the same State which, with the present ratios of increase, are liable to exhaustion in from 150 to 200 years. Anthracite coal will then be appreciated as a luxury.

We shall be told that it transcends the province of government to dictate what people shall like or dislike, or prescribe what they shall eat, drink, wear, or invest in; that the less it interferes with individual liberty, the better for society, and so on. Partisan as I am of the largest individualism consistent with the equal freedom of others, and the welfare of society, I am loath to appear as the spokesman of social invasion of personal preferences. Our duty to truth obliges us to face the facts; and there are apparently two sides to this question. The protest of Mr. Spencer and his school against such restraints is, however, a claim that one kind of want is as rational and legitimate as another, and is equally entitled to gratification. It is tantamount to saying one man has the natural right to tempt or inveigle another into buying anything he can palm off on him, and if carried to full length would not except minors, imbeciles or inebriates. We know, in fact, that the rule is not universal. The difficulty arises in running the boundaries between restraint and freedom; but daily life and administration of justice consist in drawing such distinctions. The gambler, the lottery dealer, and the pawnbroker desire nothing better than freedom; yet society does interfere with them. The underlying question for students is as to what tastes, cravings, instincts and aims contribute to the good of the race; which of them deserve to be encouraged, and which discouraged, by the state. On what other ground do all civilized nations tax spirits, tobacco and gaming implements?

In this matter of national or race prodigality, take a familiar illustration: The country boy who has been saving up his scanty hoard for a whole year to visit the

---

* An address before the Section of Social and Economic Science of the American Association for the Advancement of Science, August, 1897. Mr. Colburn is vice-president and chairman of this section.

* The assumption that in order to sell its own products, a nation must purchase a like amount from its customers is disproved every year by Brazil, which effects triangular exchanges; and by the United States, which liquidates its indebtedness by bank credits, loans and disposals of shares and titles to property. Western Europe has been swapping its fancy articles and superfluities to a tremendous aggregate for evidences of our indebtedness, calling for annual interest and dividend payments and tourists spending money of over four hundred millions. Whenever Congress is disposed to curtail this waste and bring the income and outgo into equilibrium, a chorus of importers and foreign ministers goes up that we are in danger of tariff retaliation. Having brought their emigrating customer to the verge of bankruptcy, they demand as of right a continuance, and resent any attempt on his part to get out and keep out of debt as an affront to themselves. Retaliation may be left to correct itself.

county fair, or it may be a seaside resort, has no well defined idea as to what his purchases will be for the occasion, no list of demands to be supplied; but it is certain as fate that he will part with his cash for what new or striking thing he sees, it may be gingerbread, a coasting ride, or for street fakir's wares. It is just so with the whole national merchandising. At the bottom of every country merchant's list there is, in invisible ink, the further item: Any novelty or trinket in our line that we can sell. A demand such as this is created and supplied by the same act, and articles are being urged and foisted upon callow customers far beyond their natural desires, beyond their proper ability to buy, quite in the manner of heirs to large estates, dupes of crafty cheats.

These views have been forced upon the attention of economists rather than propagated by them. Homilies against riches as hindrances to post-mortem rewards are plentiful enough; but they do little to curb ostentatious or competitive displays. It is not, however, against the truly rich the charge of profligacy is aimed so much as against those who would be thought so; by the masses who entertain the notion that respectability is an affair of outside badges, lavish outlays and make-believe. Prodigality among the rich is responsible for much of this demoralization and apelike imitation. Country homes and city mansions are tolerable, even though for the most part their owners are not living in them but occupying the hotels of both continents. Yachts, racing stables, dog kennels, wine cellars, picture galleries, opera boxes, equipages, banquets, balls, costumes, jewels, are not the delights they are supposed to be by outsiders, but paraphernalia, the implements of a course of tiresome and exhausting exercises which society imposes on its votaries for no well-defined purpose, unless it be to excite the envy of those who cannot afford them, or, an elaborate system of match making and place hunting.

"Shall a man not do as he likes with his own?" is asked. That depends. Who does not know in the ranks of his acquaintance a proportion who, in good times and bad, by a generous table, or in showy hospitality, in dress or furnishings, devour the entire income week by week; people who might be comfortable but who never will be rich, nor yet acquire any competence for old age. The example of their neighbors and the multifarious temptations of the merchants are more than they can stand. Would you then destroy the inducements for acquiring wealth? Well, yes; some of them, at least. As already explained, I would encourage self-denial and thrift on the part of rich, moderate and poor alike, until we as a people get out of debt to others; and after that to establish good roads, comfortable, sanitary homes and pleasure grounds; but not to enter upon a career of vanity and silly ostentation. I am glad to perceive in recent writers on economics a much clearer and firmer note than formerly on vicious luxury.*

V. THE BLIGHT OF PARASITISM.

Under Lycurgus, the pioneer social reformer, the Spartans held property in common. Satisfactory as the experiment was, it cannot be repeated, not even by imperial decree, without a supporting public opinion. To abolish individual property may not be possible now even by revolution, nor does it appear to be necessary or desirable, but some sort of restriction upon acquisition and transmission is desirable. "Can any man," ask the Socialists, "honestly accumulate so much as one million of dollars during his adult lifetime?" A slight acquaintance with either arithmetic or the investment of money at compound interest, or in the profits of trade, or agriculture, or pasturage, will show that he can. The familiar example of the blacksmith, who was to receive for shoeing the horse a penny for the first nail, two for the second, and so on, doubling for the whole series of 32, with a progressive doubling—not a remarkable increase for farmer, trader or stockraiser in each year—proves that he may become the owner of many millions, provided the rate of increase could be kept up for, say, a fifty-year period. The fructifying power of seeds and plants, or of domestic animals, forms the basis of about all the wealth of men and nations, that from mines, quarries and fisheries being inconsiderable. To a man not in either pursuit, it is practicable, as I personally knew a teacher to do, to lay aside one dollar per day between twenty and seventy, investing in good mortgages (formerly yielding seven and six per cent.) and the total is surprising to one who has not made the calculation, every dollar of it lawfully and honestly earned. The clamor against millionaires as such, which disgraces much of our social science literature, to say the least, is out of place. The more of them, the better—unless it can be shown that they have engrossed what belonged to others; or their use and disposition in some way contravenes the general welfare. It ought to be added that the rates of interest now being lower, five and four instead of seven and six per cent., and the profits from merchandising, farming, grazing and many forms of manufactures and transportation being halved and quartered by the competition of the larger surviving concerns, the chances of becoming a half millionaire by mere saving, without resort to speculation or usurious rates of interest, are much more remote.

Suppose we take, instead, the case of a person—it may be a bright, capable young man, a young woman, or even an imbecile ward, under guardianship—who inherits so moderate a sum as $10,000 during infancy, who, if he is fortunate enough to have guardians of judgment and probity—such a one may unknowingly become a millionaire without labor or economy. If one were able to add to this store further savings, and escape severe losses, the fortune might become very large, without encroaching on the rights of borrowers or lenders.

It is an interesting inquiry raised of late by the movement in favor of taxing inheritances now sweeping from one State to another, whether such an inheritance is honestly obtained, or if so, whether it is for the best interests of society that it so passes by descent or gift to direct or collateral heirs. The answer to this class of questions is not to be derived deductively from moral or legal maxims, but from observation in practice. The reasons for a change in the policy of inheritance and descent of large estates I have already presented to the section, at some length, and may be briefly summed up as follows:

First.—Under the régime of free competition, the desire to accumulate great wealth is not only laudable, but necessary. Business and investments are by it turned into precarious lotteries. An excess of care and fortune becomes necessary to guarantee maintenance during decrepitude, the rearing of surviving children, and support of relicts, all of which might be accomplished with less capital if more complete assurance could be had. This I am persuaded ought to be and can be furnished by the State.

Second.—The further desire to secure by testamentary disposition for offspring more than an even chance in life by setting the sons up in business, or of leaving portions or dowries to the daughters after death is neither so necessary nor so laudable, if we judge by the results. It cuts the nerves of self-reliance and engenders a feeling of "great expectations," of rewards that have not been earned; it encourages parasitism and creates sharpers and their dupes, stimulates fortune hunters, and multiplies marital misery. Besides, it is contrary to good morals and sound policy to hold out the hope of advantage through the death of another, whether he be of near or remote kin. The profligacy of heirs to large fortunes, the demoralization and degeneracy of spendthrifts and their retinue need no amplification. As a contrivance to secure the marriage of daughters, it is remarkable at present chiefly for the success of the money bait in attracting the needy or degenerate holders of titles to nobility, and is no improvement on the plan mentioned by Herodotus where the more comely maidens were annually bid for at auction, the premiums going to the less attractive to whatever extent was necessary to secure a consort.

Third.—The difficulties attending succession are by no means so trifling as they may appear to those who are not put to the trouble. Public sentiment, following custom long established, dictates that a man's possessions shall be divided among his own children and blood relatives, with a reservation in favor of his widow, if there be one; and the statutes have been framed on that policy in cases of intestacy. The courts are more and more inclined to interpret ambiguous phraseology to that end, and to annul wills, or portions of wills, to the contrary tenor, except upon the clearest declaration of intention and choice of instrumentalities. This is an attempt to curtail that plea of "undue influence" which forms the basis of most testamentary contests, and which breeds scandals, family quarrels, and wasteful litigation. In olden times there was hardly a possibility of a large estate being passed without a liberal slice to the church, and many States have expressly limited the share which may thus be awarded to those not of kin or to eleemosynary institutions; others have suggestively forbidden bequests to priest, doctor or counsel in attendance during the last illness.

The draughting of probated wills reveals a disposition to withhold the principal sum from children, for which trustees are appointed, giving merely the income, the capital going to the grandchildren as being perhaps less likely to misuse it than their parents.

Fourth.—The bequests to charity, though undoubtedly in many instances perverted to founding and maintaining useless sinecures, are not so numerous nor so large as to constitute a menace to society. Contrariwise, they should be encouraged and made more general, and be more effectively carried out. At the same time the attitude of mendicancy is not favorable to manly independence or intellectual vigor, either on heirs of the blood or on institutions (unless scientific research be an exception). Philanthropic aims may be rendered more certain either by concentration into systematic method or by oversight and positive regulation from an exterior authority. It is a hopeful sign that the endowments, formerly going exclusively to churches and missionary efforts and the like, are now going more and more to technical and scientific institutions.

Fifth.—I need not discuss here the power, or the wisdom, of taxing legacies by the State; it is here, and promises to remain and grow. The only question for the sociologist now is: Shall the very considerable revenues derived from these sources be mingled with the general treasury and be expended for any or all State purposes, as in New York and many States; or, shall an effort be made to segregate this money and dedicate it to special purposes of benevolence, charity, and embellishment, thus to invite and, if wisely carried out, to win in advance the consent of the owners of large properties? I believe it is in the power of law, and within the compass of economic skill, to provide a residuary legatee for every such person superior to any other he could choose or contrive for himself, so that, in fact, it would practically make no difference whether he executed a will or not; or, if there were any difference, that the machinery provided by the State would be more sure to meet his views than any he could select. Nothing would prevent him from distributing his estate during life, if he felt so inclined; but, on the other hand, a portion of all beyond what was necessary to a competence to infants, to the disabled or incompetent, would be turned over to a department of beneficence, managed by skilled men, as are our State universities and the Smithsonian Institution, who should organize and methodize the philanthropic impulses of the rich with the ample revenues at command much better than the haphazard litigious course now open to them.

Sixth.—The same agency thus intrusted with the dispensing of voluntary as well as involuntary bequests might be availed of to do away with much of the necessity for hoarding or amassing riches, and to strip from great wealth some of the dangerous or mischievous homage paid to it, which is the cause of so much friction and clashing in lives that otherwise might be serene. Annuities might be granted for the life of the purchaser or for the life of others, objects of his care and solicitude, and thus help to banish in large measure the fear of the wolf at the door. The vicissitudes of business and health, the disappearance or loss of friends, the impatience of consanguines with enfeebled dotards, are all real causes for morbid acquisitiveness, and these might be banished by a pension or competency for life. Steady, though moderate, income is conducive to longevity, sanity and tranquillity.

By such means the benefactor who is frequently at a loss what to do with his possession could have the double benefit of using it up, or all that was of any real use to him, and at the same time of seeing the remainder of it devoted (without the scandalous shrinkage which now attaches to many of our pet charitable societies) to the erection and conduct of hospitals, asylums, reformatories, libraries, Carnegie and Cooper Institutes, memorial statues and edifices, public parks and promenades, music halls and pavilions. I hold it certain that the most avaricious of heirs would sooner see the contested wealth expended in such a judicious manner than on court costs, lawyers' fees, and the like, or than given to the opposite side. If it be objected that inheritance taxes will be evaded by gifts during life, it is easy to see that this is one of the objects aimed at—to coerce rich men and women to dispose of their excess beyond the line of competence, and to see the good or ill it works and not leave this task wholly to surviving society. There ought to be a narrower limit drawn around the power of the dead hand. Because of the sagacity to amass a fortune, there is no reason in nature why that fact should carry with it after death an authority greater than to the living.

VI. THE RÔLE OF SUPERSTITIONS.

Here let me say, we speak commonly of the sciences as if they were so many separate and independent fields of work, with distinct boundaries between them; and the division of these studies into so many different chairs in our universities, and our own classification under ten or twelve groups or "sections" tends to confirm this supposition. It should be understood that science is systematic knowledge, and the pursuit of knowledge according to methods admitting of demonstration or reasonable certainty; and that each portion is not only interlaced with its near neighbor, but all are more or less blended and interdependent, so that any great advance in one affects the others, and, of course, any backwardness keeps back the near related parts.

The old conception of science as a pyramid, whereof languages, mathematics and geometry were the basis and philosophy and theology the apex, we must now disavow; nor is it that of a circle where the several sections could be evenly joined together or taken apart, or the conception of a linear prolongation as of a tree, or vine, having roots, stem, branches and twigs, a true image. They are merely convenient symbols, but if accepted too strictly, they are apt to mislead. The present classification, like many it has displaced, is provisional and subject to reformation as a whole, as are also the component parts. While mathematics and geometry remain substantially on the bases laid out in the infancy of science, other studies, such as astronomy, geology, physics, chemistry and biology, have been completely recast; nor ought we to suppose that a finality has been reached; indeed, there are signs that portend a reconstruction to bring them all into more harmony. From his psychical, purposive and co-operative nature, man himself must always be entitled to a large and somewhat exclusive space in scientific labors in any scheme of science. Social science has not yet had its methodical reconstruction. Occupied, as it must be, largely with men's wants, motives and passions, it is essentially psychic, and awaits the evolution of the new psychology—just now renascent—before it can claim to be a science of precision and prevision. Meantime, there is much to be done; the very terminology and nomenclature, framed on the old traditional theories, will require to be abandoned or charged with new meaning to fit them to new conceptions.

It begins to look as though the wrong road had been taken in psychology, and that very much of the confusion, clashing and misery of the world is traceable to the error. It does no good, for instance, but harm, to assume as the text books do, or did, that mankind alone exemplifies the social faculty; that he alone is capable of mental development; to deny a mind or soul to the other animals, when they exhibit such human emotions as affection, fear, anger, grief, jealousy, gratitude, avarice, shame, deceit, coquetry, feigning, dreaming—attributes proceeding, so far as they go, on lines parallel to those traversed by all men in the primitive stages and by some men up to this day, but whom, on account of their backwardness, we call savages.

There is, therefore, a human and a subhuman psychology, and (if mere aggregation or association of effort and action is to be accepted as a distinguishing line of division) a subhuman sociology also, so nearly related that continual reference may be made from one to the other, as in the case of comparative anatomy and pathology. For that wide segment of psychic activities peculiar to man, in which there is not merely a consciousness of likeness, of community of burdens and pleasures, but also social purposes, aims and organized

* "The rich have their responsibility here and their duty. Wealth and culture have a special service in their saving influence toward higher standards of thought and life and away from the raging materialism of modern society. And note that the distinction is world wide between luxury and ostentation. That which the rich desire for itself and not as the badge of precedence or the target for silly envy, they may well have—but only on condition that they rather hide than flaunt it. Society is greatly in need of lessons in plain living and high thinking. It is a fallacy to suppose the wastes of the rich are necessary for the employment of the poor. The consumption of the rich determines whether the laborer shall produce this or that, and not whether he shall produce at all. If the rich refrain in some measure from consumption, their savings profit society under the form of capital in the production of a larger social dividend. But the changing demands of vanity stand to society for more than waste and overwork. They corrupt art, they confuse and disturb the organization of industry. First, they corrupt art; no beautiful fashion, if once attained, is safe to stay. If grace and simplicity come as fashions, they go as fashions. The greed of novelty leaves the beautiful behind as antiquated, to be succeeded by the ugliness of hoops and wings. From champagne to plumes of slaughtered birds, from skunk skins to jewelry, there is nothing permanent but novelty, no custom but change. And note that as soon as nothing in art which is good can abide, there will be nothing really good. When the best work can have but a butterfly life, there will be no best work."

"It is at first thought odd that unrest should especially mark the nineteenth century. The world is rich and growing richer, and wise and growing wiser. Never before would a day's labor bring so many dollars or buy so much. . . . A larger, wealthier life is open to us, and it ought to be a greatly happier life. And yet we ask ourselves what does it all profit? Pass rapidly over in thought the question whether with all our centuries of achievement we are so greatly better off than the Greeks without. Is the greater rush and push of life a good thing in itself? What does it mean that the insane asylums yearly build larger for minds unstrung by tension? How about the multiplication of suicides? Likewise our prison populations are not disappearing as the good things of life become cheaper, but theft somehow grows out of plenty.

"There is a grim paradox in civilization somewhere. Wherein do we fail, or waste, or misuse? How is it with all our opportunities? Our harvests somehow do not altogether shield us from hunger or our looms from tatters. What does it mean that as science grows and wealth multiplies, the cry of poverty swells louder and louder, and that discontent is the fatal malady of our civilization? . . . Splendor, no matter how much labor it has cost, is not splendor when it has become general. All may as well stand still as run in an equal race. Thus, material progress, so far as it is directed to competitive show, expends itself in a strife for precedence. There is no share of gain in it for any one which does not stand for discontent and heartache for some one else. All ostentation is waste from the point of view of society as a whole. For the poor it aggravates their poverty."—Davenport: "Outlines of Economic Theory."

or systematic social efforts, in which primitive society is conspicuous (individualism being a later growth), combining plans for security, comfort, enjoyment, aspirations, opinions, creeds, culture, interdependent arts and industries, we have no better name than civilization. That I take to be the cement which binds together individuals in a relation external to that of consanguinity or ethnic derivation. There are archaic types of this culture existing contemporaneously with the modern advanced ones, the strata being curiously intermixed and overlapping barbaric traits cropping out everywhere upon civilization. The most convenient line of separation I can think of between them for the purposes of specialty subdivision is that of literature, the writing faculty being the earmark of the civilized and the lack of it of savage peoples.*

In speaking of the passion for fighting, you will notice I endeavored to account for it as being derived mainly from ancestral experience and as a trait common to man and the lower animals. We make no difficulty about accepting this explanation of those exhibitions of the mind faculty we call instincts; but in regard to the higher faculties, such as reason, will, selfconsciousness and the like, the philosophers have hitherto followed a different but not very satisfactory explanation, and have sought to reserve them to man alone. It is only within the recollection of those now living that any attempt was made to study the mind with the same freedom as any other phenomenon, and to reduce it to an experimental and comparative method; that is to say, for upward of two thousand years the notion of the duality of man had held the field, and any profane meddling with the soul, as the invisible self, ego, or personality, was deemed sacrilege, and would have met with ecclesiastical censure or penalties. The idea that the soul was something more than a function of the organism and appurtenance to it, was per se an entity, lawless, independent, directing, initiating and controlling the bodily movements and capable of maintaining a varying struggle with the passions, emotions, instincts and intellect, was probably derived from Hindostan (although the more consistent doctrine of successive incarnations by the same immortal soul was somehow dropped out in the transit) about the time of Socrates and Plato, and to them and its engrafting on the Jewish mundane religion we may attribute this long fencing off of mental phenomena from scientific observation. The plodding German metaphysics has done much to befog and encourage this cult of separable states of the mind and personality.

There are other traits besides the combative to be traced back to this race experience, such as the awe of the dead, or death bed and burial, the sense of duty or "oughtness," the propensity for lying and stealing, styled "original sin," the feeling of premonitions and of a previous existence, the craving to penetrate the future. Out of these ingrained mind traits metaphysicians have sought to construct "forms of the understanding," "categorical imperative" and innate ideas, dictates of conscience, and from these various systems of philosophy and ethics. Indeed, the claim is still maintained that there are two kinds of truth, the intellectual and the spiritual, and wherever their conclusions differ, the latter is entitled to superior validity. Confusion is thus introduced; and we have the further claim of lifting faith above knowledge, and that religion and its bases have a sphere of their own from which science is excluded. This claim scientists have not taken pains to deny, for science need not hurry, but it concerns them deeply to resent it. While the spiritual theory is defective, I am not disposed to accept the more recent one of the genesis of religious ideas from dreams, ghosts or ancestor worship. These are supporting afterthoughts. The natural wonder as to the first breath of the newly born, the last breath of the dying, the heart throb, ecstasy, suspense of consciousness, decay of mental powers, sportive variations, have helped fasten the notion of a lawless and independent double or shade which, once accepted, has led to all manner of excrescent amplifications.

Underlying this guessing at the mysteries of life, the whence and the whither, the how and the why of it, we may trace alike in man and in brute an impulse of mind or instinct which is phylogenetic, rather than ontogenetic; it belongs to the chain of descent rather than to the last individual links, in which we may discern the germ of all religious emotion. It is analogous with the embryonic progression through lower forms of structure. I mean the inborn propensity of making believe, of personification, and of poetizing in the original signification. This is the true fetishistic basis and bias; it extends to things animate and inanimate, especially if they have some semblance of animate forms. Doll inventing and pet loving are early exhibitions of it, and symbolism in art, image worship and ritualism are later ones. The inherent tendency to apostrophize, to endow or discover life or character, and to reverence is common to savages and to the children of the civilized, and is slowly outgrown by the former; while it lingers in poetry, folk lore and superstitious observances among the latter. Essentially an emotional and feminine trait, it fades with experience and the light of reason; it is probably a vestige of the period when vocal utterance was but feeble and crude and when ideas were conveyed chiefly by signs, mimicry and gesture; the gestures of obeisance, supplication and tenderness being then, as now, very impressive. Such is, I believe, the origin of worship. It has a close analogy in the palimpsestlike reappearance of old and forgotten shadows on the sensitive plate of photography after they were supposed to have been erased and then over-laid with more recent films. Religious ideas had a large use and significance in the infancy of the race and will continually crop out in spite of the culture of later time. In this respect the venerating or worshiping impulse may be likened to the sensation experienced by dramatic recitals, the excitement of the dance or the soothing of rhythmic sounds, the exhilaration of rapid motion; the instinctive clutch of the infant which cannot have experienced a fall; the lingering passion for fishing and hunting; or, to take an extreme illustration, the excited aversion of a kitten at the first sight of a dog or at the first smell of a mouse. By the light we now have we are permitted to offer a physiological explanation of phenomena of mind heretofore quite mysterious. Such puzzling phenomena as hypnosis, fascination, coincident cogitations, double and alternating consciousness, are to be solved in this way.

The time was, not so long ago, when the physiologist would hardly entertain the soul as a subject of speculation, not even in disease, insanity being accounted as possession by devils. The physicist would have thrown it out of his laboratory window, if possible. The labors of anthropologists helped greatly to lead out of that old rut. The study of mind in the multitudes, of the savage, of race traits, of mythologies, folk lore and religious ceremonies betrayed their true origin, and disclosed the likeness of origin and especially the regularity of sequences we call "laws" of thought. The biologists still further broadened the base of psychology by tracing it down through the gradations of organization to the cell, and into plant life; nor is it certain that it stops with life, as we at present define life, but seems to be coextensive with organization.*

Science does not, in one sense, concern itself with teleological suppositions; that is to say, it is reluctant to resort to any of them to explain the observed cosmos, and prefers to listen in a neutral attitude to the rival philosophies—theism, manicheism, atheism, monism, spiritism or materialism; but it is at least equally well equipped to pass judgment on any such speculations as their advocates. The attempt to waive students off from the domain of the soul or from religious beliefs and observances is likely to be disregarded. In fact, the educated ecclesiastic mind now anxiously awaits the verdict of science on the nature of mind, and the origin of some of these innate ideas. When it is found that they are naturally accounted for as belonging to the experience of the race, something not to be ashamed of and still less to be proud of, and are not likely to be superseded very soon, the doctrine will be welcomed as one averting a threatened dissolution. So long as the perpetuity and acceptance of the church dogmas was based upon the inspiration of certain writings, upon miracles, upon special providences, soul peril and soul rescue, or future rewards and punishments, it was exposed to the double risk and cross fire of successful contradiction by science, and by historical criticism, and also liable to the ridicule of scoffers and the charge of outrageous fraud. Science is now on the eve of supplying a broader and more enduring, or at least less precarious, basis for religious ideas than its votaries. When Pope Pio Nono was told that science was undermining some of the foundations of the church, he exhibited a profounder knowledge of human nature and soul nature than the casuists by his reply: "Then we must revive more relics and shrines."

Dr. Andrew D. White has rendered a special service to scientific research and also to ecclesiastical training by his compilation, with abundant citation of textual proof, of the successive awkward retreats from this position of superior spiritual discernment. Whenever the psychologists are ready with the lacking capstone of experimental observable proof as to the act of thought, the further measurements of its velocities, and transformations of matter or motion into that we call consciousness, they will be listened to with profound attention. No propaganda is needed to enforce the conclusions of science, the intelligible statement is enough to overcome the most unscrupulous opposition. What is now waited for is a psychic spectrum to throw as upon a screen the analysis of mental phenomena and to give the equivalent of Fraunhofer's lines in perception, memory, comparison, association, ratiocination, the several emotions below and above the limits of consciousness, and especially to picture for us those puzzling subconscious states the mirages of the will and the self-examination. We may confidently expect (probably from another rash layman) some form of mental bolometer which shall record for us the dimensions and count the number of the vibrations of this hitherto unsuspected mode of motion, if not also to disclose those delicate films which carry some but not others of those external stimuli down to posterity, and fix the stamp of ancient habits, passions and character long after their necessity or utility has vanished. Is it any more wonderful than that the two forces of heredity and environment should preserve the bodily forms and organic structure for a like period? After the publication of Haeckel's famous work demonstrating that man himself in embryo, and often in life, bears the evidence of derivation from, and similarity of nature with, the lower animals, it is not incredible that these mental traits should accompany them for the latter part of the period. As passing from mother to child, we accept them along with the physical features unquestioned. We easily detect them for three or four generations. Why not for ten thousand composite impressions? One is tempted to use the exclamation of Huxley after his first reading of the "Origin of Species:" "Why, how stupid of us that we never thought of that before!"

The retrospect extending so far back enables science to look forward a trifle. The decay of faith, and the crumbling of dogma already giving anxiety to thoughtful men within the ecclesiastical pale, is giving rise to the question: "What is to become of morality when its supernatural sanction is lost?" Prof. Goldwin Smith, from the historian's point of view, naturally apprehends a serious jolt, and doubts whether the present structure of society can stand the transition. The view here taken may reassure the timid. The doctrines which are causing such naïve embarrassment: the fall of man, the atonement, the resurrection of the body, the real presence, anthropomorphic deity and filiation, angels, devils, future rewards and punishments, may fade out and disappear—may, in fact, be relegated to the region of extinct mythologies—but the underlying religious idea, the worshiping instinct, will remain. It is as perennial as the belief in fairy tales, nuptial revels, bereavement, serpent fear, omens, portents, myth making, charms, amulets, lucky stones, and ceremonial superstitions; and having the same ingrained origin. They are vestigial experiences of the race—an inheritance to be outgrown, but meanwhile costly impediments.

RORIG'S LAMP FOR THE DESTRUCTION OF INSECTS.

DESTRUCTION OF INSECTS.

THE problem of the destruction of noxious insects is more difficult of solution than might be supposed. Insecticides are found inadequate, sulphide of carbon, nicotine, emulsion of soap, tar, essential oils, naphthaline, petroleum and sulphate of iron, not to speak of secret compositions, have been recommended. Despite everything, the ravages continuing to increase, the public authorities have occupied themselves with the question. A decree of December 24, 1888, concerning the destruction of insect pests, replaced the old law as to the destruction of caterpillars that was but slightly or not at all enforced. After insecticides, a trial was made of traps and other apparatus designed for capturing moths, flies, butterflies, beetles, etc., by the wholesale. On another hand, M. Finet has devised a permanent evaporator, composed of a glass bottle having a lateral aperture closed by a cork, and which is suspended from the branches of a tree after being filled with a peculiar insecticide. These bottles, to the number of one per square meter, are placed on plantations.

M. Martre invented the tannophore, an apparatus designed to disengage vapors of tobacco juice in greenhouses. But these processes are used locally only. It was but natural to think of utilizing the influence of light and fire upon insects.

M. Gaillot constructed a very popular automatic torch for the destruction of the nests of caterpillars and plant lice. Then a return was made to lanterns, which are sometimes obscured by clouds of phryganids, phalenids and ephemera.

In certain districts it is customary in the evening to light bright fires into which moths and other insects fly and are burned. These curious experiments have been put to profit to effect better work still.

Trunks of trees, boards and vessels have been smeared with honey, molasses and other saccharine substances to which the insects adhere when they come into contact therewith.

In the Journal d'Agriculture of August 20, 1892, we find a description of a trap for the destruction of the cochylis, devised by M. Besnard, of Paris. Two or three of these traps to the acre are sufficient, it seems. The apparatus consists essentially of a lamp surrounded with a conical frame of galvanized iron wire smeared with bird lime, which captures lepidoptera. It is not only moths that can be destroyed in this manner, but also all nocturnal lepidoptera and coleoptera. But, among the new methods that are most apt to give entire satisfaction, we believe that one of the best and most practical is the apparatus invented not long ago by Dr. Rorig.

The following is a brief description of this apparatus, which we illustrate herewith:

A lamp is inclosed in a hexagonal lantern, every side of which contains an aperture which is provided with a strong lens preceded by a conical reflector through which insects, attracted by the light, can enter. At its upper part the lamp is formed of a pyramidal cover provided with ventilators that allow of the exit of the hot air, but preventing the escape of the insects. It is closed at the bottom by a pyramidal base that leads to a reservoir into which is put a saccharine and odoriferous mixture that attracts the insects. The latter, after entering the lantern, are unable to make their exit therefrom and slide into the lower receptacle, which it suffices to empty from time to time. The diameter of the lantern is 0·31 m.; the sides are 0·15 m. square, and the diameter of the front aperture is 0·13 m. The instrument is placed in a tree or in the open field.

The expense of keeping the apparatus in working order is very small. The present price of the lamp, however, is too high to allow the use of it to become

* If the present classification is to stand, anthropology covers all human affairs and thoughts—a field too vast for a single cultist to master in all its detail. Ethnology, archæology, somatology and spoken languages would seem to belong to it somewhat exclusively. How, then, are the remaining human activities to be divided, such as civics, politics, demography (vital statistics), economics, ethics, esthetics, arts, industries, education, creeds, opinions, folklore, linguistics? Dr. McGee, in a very commendable scheme of anthropology, has used the word sophiology as a generic title for the more psychic of these, which seems to me to be a more scientific and more natural line of cleavage (and one which will appeal to the sense of responsibility of the council) than sociology—a hybrid at best, which not even the brilliant sponsorship of Comte, Spencer, Giddings, Small and others in professorial chairs can reconcile with other sciences. Any arbitrary line of separation is attended with difficulty; but if these studies could be divided into two or three departments, it would tend to reflect the present trend of research.

* For opinions on the coextensiveness of mind with life and organism see Haeckel's "Creed," E. D. Cope's "Primary Factors of Evolution" (concluding chapter), Darwin's letters, Clodd's "Pioneers of Evolution," Romanes and others, Neo-Lamarckians and Neo-Darwinians.

For expressions on the pervading reach of mind, as exhibited in unorganized matter—as a property of matter—in the curious behavior of substances like camphor grains, gamboge, frost crystals on plate glass, figures on vibrating membrane, see current literature of physics and chemistry, Prof. A. E. Dolbear's "Matter, Ether and Motion," also the concluding sentences of his lecture at Wood's Holl Biological Station: "At any rate it is evident that if any such theory of matter as is here presented be true, and if the behavior of matter as we see it in the test tube and microscope has been interpreted with any approach to the truth, then it is a much more wonderful thing than the old philosophers thought; its possibilities greatly exceed what could before have been imagined; and if mind itself requires a material habitat, then it has in an atom an imperishable living home."

common. It would be easy to simplify it by adopting a less costly arrangement, and farmers might then use it with great profit.—La Nature.

THE PUNIC NECROPOLIS OF DOUIMES, CARTHAGE.

TOWARD the end of the summer of 1893, the Rev. Father Delattre began a series of excavations at Douimes, Carthage, which resulted in the discovery of an interesting and extensive necropolis. By the month of November of that year he had opened upward of sixty tombs. One of these, discovered on November 28, was

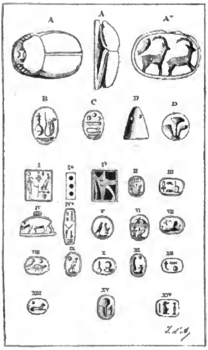

FIG. 1.—CARTHAGINIAN SCARABÆUS AND AMULETS.

double, and constructed of beautiful slabs of tufa, the only kind of stone employed in the primitive Carthaginian structures. Each compartment was 2·05 m. in length, 0·75 m. in width and 1·10 m. in height. The two mortuary receptacles were put in communication by an aperture in the median partition. In one of the compartments there were found, in addition to the usual objects (double urn, amphora, lamp and patera), alongside of the skeleton, two nearly hemispherical vessels with a conical appendage upon the belly, a ring, and a scarabæus bearing three hieroglyphic characters reading: "RA is the true ichneumon"—an allusion to the worship of the ichneumon and to its identification with RA. The Egyptians, in fact, worshiped the ichneumon or Pharaoh's rat (Herpestes pharaonis).

The scarabæus in question is reproduced in No. VIII of the accompanying Fig. 1. The following is, according to M. Maspero, an explanation of the pieces reproduced in this figure: B and C are scarabæi carrying a device that had no meaning except to the possessor.

FIG. 2. SCARABÆI

D and D' represent a cone worn as an amulet. At its base is seen a tuft of lotus.

The rectangular tablet that carries the first number is of a whitish material and provided with three apertures. One of its faces shows the "oudja" or eye of Osiris, and the other bears a scene of Egyptian mythology thus interpreted by M. Maspero:

The goddess Sokhit, crowned with the disk, a scepter in her hand. Her name is written in front of her. In front, the banner name "Horou âa hiti," the magnanimous Horus of Pharaoh Psammetichus of the XXVIth dynasty.

M. Maspero remarks that this very delicately executed amulet certainly gives the highest limit to which we can carry the age of the tomb in which the object was found.

Psammetichus, who founded the twenty-sixth dynasty, was one of the twelve kings who divided the government of Egypt between themselves after the death of Pharaoh Sethos, whom a statue represented, rat in hand, with this inscription: "Learn by my example to respect the gods." It was doubtless the ichneumon that Sethos thus presented for the veneration of the Egyptians. Psammetichus reigned from 671 to 656 B. C. over the northwest part of Egypt, to the east of the Delta. He succeeded in driving out his colleagues, and afterward reigned alone until the year 617. It is related of him that he built temples at Memphis in honor of the bull Apis and of Phtah. This Pharaoh called foreigners to Egypt, had a navy organized and tried to conquer Phenicia.

These details show on the one hand that the tomb that contained the amulet above described cannot date back further than the seventh century before the Christian era. This, moreover, will establish the date of the most ancient objects found in the necropolis.

Scarabæus No. II. Upon the corbel is seen the

FIG. 3.—GOLD EARRING AND NECKLACE BEAD.

cartouche of Menkaouri (Mycerinus, the Mycerinus of Herodotus and the Mencheris of Manetho), the founder of the third of the great pyramids of Gizeh. Above is the title, "Horou noubi," the Gilded Horus, the Victorious Horus and the goddess Sokhit with the lioness' head, in the same posture as in the preceding number.

The style, says M. Maspero, indicates the "saite" epoch. The name Menkaouri, like that of Thoutmosis III (Mankhopirri) or of Amenothes III (Nibmaouri), was reproduced at all epochs by way of an amulet, on account of the mystic sense that it possessed.

No. III. Isis Onkhit, "the living one," a female proper name or one dedicated to the goddess Isis, whose name would be followed by the frequent epithet "onkhit," the living one.

No. IV. Amulet in the form of a sow or hippopotamus. Upon the plate is read: "Phtah, good messenger who protects the entire earth (Egypt)."

No. V. The god with hawk's head, and the hawk of RA upon the corbel.

No. VI. Har-Khobi, Horus of Bouto, upon the corbel. M. Maspero seems to think that the winged disk transformed into a bird proves the Phenician origin of the object.

No. VII. Sphinx. The characters above may be Phenician. They have not been deciphered.

FIG. 4.—CARTHAGINIAN LEAD WEIGHTS.

No. VIII. This is the scarabæus already spoken of. We read here: "RA is the true ichneumon."

No. IX. RA and Horus upon the corbel, a formula having no signification except to the owner.

No. X. "RA is the good master."

No. XI. Nebmâiri, "a master of the truth is RA."

No. XII. Name of the moon god Thebain, son of Amon and Mout.

No. XIII. RA or the sun god and a lion.

No. XIV. The cynocephalus Thot, whose voice enchants by its magic power.

No. XV. The disk of the sun surmounted by two feathers.

The description and sense of these few scarabæi show the relation that existed between Egypt and Carthage from the view point of customs, religion and commerce.

The excavations were continued at intervals between December 29, 1893, and January 31, 1894, and besides the usual objects, there were discovered some Greek vases, some unguentaria of glass and alabaster, some ostrich eggs, some copper and bronze mirrors, some earrings (Fig. 3), some amulets, and, finally, two bronze scale pans and a series of lead weights. These weights (Fig.

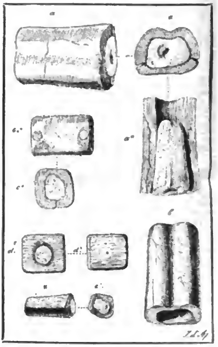

FIG. 5.—CARTHAGINIAN BONE WEIGHTS WITH THE ADJUNCTION OF LEAD.

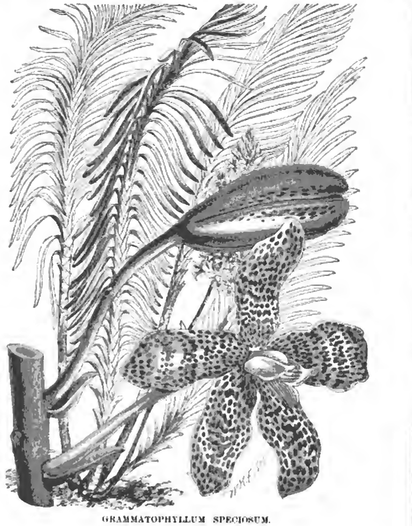
4), which were nine in number, were all truncated pyramids in form, and of square section. Six of them were marked with a peculiar sign. The following were their respective values in grammes: 196·8, 96·7, 44·6, 24·6, 11·18 and 9·12.

The first set of weights found in the Douimes tombs was of lithographic stone of a greenish color and smooth and soft to the touch. It consisted of six weights. The largest of these was rectangular in form and weighed 89·8 grammes. The others were of the form of a truncated pyramid, with the exception of a round flint stone, which appeared to have replaced one of the weights wanting in the set. The respective values of the weights, in grammes, were 45·45, 23, 11, 42, 4·65 and 25. The smallest weight was marked with the Punic letter eh. The signs that the others bore were not alphabetic characters.

Another set was of bone with the adjunction of lead (Fig 5). In view of the material, the value of these weights could not necessarily be as exact as that of the metal or stone ones. The following are the respective values of them in grammes: 99, 35·2, 19·8, 12·5, 8·4 and 3·15. For the above particulars and the accompanying engravings we are indebted to Cosmos.

GRAMMATOPHYLLUM SPECIOSUM.

THE event of the week, horticulturally considered, has been the exhibition of a noble spike of this orchid by Sir Trevor Lawrence. An idea of it can be gleaned from our figure, repeated from a former volume. At the bottom of the spike in Sir Trevor Lawrence's plant were two abnormal flowers, one of which is figured in our engraving. This flower had four nearly equal segments in two rows—no true lip and a straight column—a very common state of things among orchids, and interesting as showing the probable derivation of the ordinary irregular orchid flower from a regular type. The plant is recorded to have flowered first in 1851 in Loddiges' nursery at Hackney, while a much finer specimen appeared in 1859 in the garden of W. G. Farmer, Esq., Nonsuch Park, Ewell, and subsequently another was flowered by Mr. Scott, gr. to Sir G. Staunton, Leigh Park. Mr. Curtis, of Penang, a few years since sent us a photograph of a magnificent plant of this species of dimensions that we hesitate to cite. Unfortunately, the photograph was unsuitable for reproduction. Another fine but much smaller specimen was imported by Messrs. Sander & Company, of St. Albans. We gave a figure of the extraordinary snakelike pseudo-bulbs denuded of leaves, and with its curious ascending roots, at the back page of the index for vol. xiii, 1893. This specimen was presented to the Royal



GRAMMATOPHYLLUM SPECIOSUM.

Spike 7 feet high; flowers 5 inches across.

Gardens, Kew, by Messrs. Sander, and forms now one of the most striking objects in the Victoria house. The roots have access to the water, and the plant is in vigorous health, and will no doubt flower in another season. The plant is a native of Java and other islands of the Indian Archipelago. The prevailing color of the flower is dull yellow, thickly dotted with reddish purple spots. The pseudo-bulbs attain a height of 9 to 10 feet, and the flower scape measures 6 feet and upward in height. The flowers measure 5 to 6 inches across.—The Gardeners' Chronicle.

[Continued from SUPPLEMENT, No. 1134, page 18132.]

THE SPREAD OF LAND SPECIES BY THE AGENCY OF MAN; WITH ESPECIAL REFERENCE TO INSECTS.*

By LELAND O. HOWARD, Ph.D.

IN considering the question as to the regions with which an interchange of forms is most likely to occur, it is obvious that they are those which have the greatest similarity of climate, and, most nearly, identity in point of time of seasons; those, in fact, which are most likely to afford similar environmental conditions. A study of the similarity of faunas and floras already existing will lead us to the same result. Wallace has pointed out that with the Coleoptera the best marked affinities between regions are those between the Nearctic and the Palaearctic, the Oriental and Australian, the Australian and the Neotropical, all of which appear to be about equal in each case. Next comes that between the Ethiopian and the Australian on the one hand and the Ethiopian and the Neotropical on the other, which also appear about equal. Then follows that between the Nearctic and Neotropical regions, and lastly, and by far the least marked, that between the north temperate and south temperate regions.

Further, in the consideration of accidental commercial importations, the amount and frequency of commercial interchange and the rapidity of the journey are most important factors.

From all of these considerations combined we arrive at the conclusion that the regions with which accidental interchange of species should be most frequent are Europe and North America, and this is with insects to a certain extent borne out by the facts. The introduction of species from Europe into North America is of everyday occurrence and their establishment is far from rare. The carriage of American species to Europe is an equally frequent matter, but their establishment is much less frequent.

I have studied in this connection—my profession being that of an economic entomologist—principally the species which are prominent as injurious to horticulture or agriculture or in other ways inimical to man. Listing the insects of prime economic importance in the United States, the species each of which almost annually causes a loss of hundreds of thousands of dollars, we find that they number seventy-three. Of these thirty are native, while thirty-seven species have been introduced, six species being of doubtful origin. Of the thirty-seven introduced species, thirty have come to us from Europe, all, with one exception, as accidental importations.

Of the prominent European injurious insects, on the other hand, but three are said to have come from America; the grapevine phylloxera (Phylloxera vastatrix), the woolly root louse of the apple "American blight" (Schizoneura lanigera), and the Mediterranean flour moth (Ephestia kuhniella). Of these but one is certainly American—the phylloxera. The origin of the Schizoneura is somewhat doubtful, while the Mediterranean flour moth is not American, but probably came to us from Europe, although originally it is probably Oriental

As with these insects of prime economic importance, so it is with other less noted species. There have been rather frequent establishments of European species in America, but practically none of American species in Europe. The reason for this curious condition of affairs is difficult to find. The general trend of accidental importations seems to have been westward, and it is doubtless a fact that certain of our now cosmopolitan forms were originally Asiatic and have traveled westward, through Europe, to and across America, and thence to Hawaii, New Zealand and Australia. The existence of such a law is borne out in the study of plants as well. The statement just made regarding insects of prime economic importance is almost exactly paralleled with the plants classed as weeds. It has thus been shown that, out of two hundred American weeds, one hundred and three are introduced, of which ninety-six are from Palearctic regions, sixty-eight being native to Europe, while it seems that less than half a dozen American species have become troublesome in Europe. A number of American species, however, have been carried to Australia and flourish there with vigor.

This general trend from east to west has always been in the direction of the newer civilization—from the older civilization to the newer. That this in itself is significant cannot be doubted, and in the case of the insect and plant enemies of agriculture the facts surrounding this condition are almost in themselves sufficient to account for this direction movement. I have shown in another paper that the denser population of the older countries and the resulting vastly smaller holdings in farms, the necessarily greatly diversified crops, the frequent rotations of crops, together with the clean and close cultivation necessitated by the small size of the holdings, and the cheaper and more abundant labor, will all operate as a barrier against the establishment of injurious species, while the reversed conditions in a newer country at once liberate an introduced species from the repressive conditions which affected it in its original home and encourage its establishment, multiplication and spread. But there are deeper causes than this at work. It has been suggested that the flora and fauna of America, the older continent, have become degenerate through age and cannot successfully resist competition with the more vigorous forms introduced from the younger continent of Europe,* and that there are not yet formulated climatic differences favorable to the development of Palearctic forms on the American continent; but these theories seem unsusceptible of proof, and for the present we must content ourselves to accept the facts as we find them.

The insects which are accidentally imported are carried in three main ways. Either (1) they are unnoticed or ignored passengers on or in their natural food, which is itself a subject of importation, such as nursery stock, plants, fresh or dried fruit, dried food stuffs, cloths, lumber or domestic animals; or (2) their food being the packing substances used to surround merchandise or the wood from which cases are made, they are thus brought over; or (3) they may be still more accidental passengers, having entered a vessel being loaded during the summer season, and hidden themselves away in some crevice. The coleopterists (Hamilton and Fauvel) make a distinction by name among these classes, calling the first group "insects of commerce" and the latter "accidental importations."

It would appear on the face that these more strictly accidental importations must be rarer than those which are termed commercial importations, yet of the 156 introduced Coleoptera recorded by Dr. Hamilton in 1889, sixty only were considered by that writer as insects of commerce, while 96 he thought had been brought over in this accidental way.

The remaining Coleoptera common to North America and the Palearctic region, 278 in all, Dr. Hamilton considers to be practically circumpolar species, or at least not imported. Fauvel in his remarks and additions to Hamilton's catalogue raises the number of non-introduced or circumpolar species to 306, leaving 125 as imported, of which only 28 appear to have been imported from temperate Europe, the rest being cosmopolites or subcosmopolites. Of the latter class he thinks that 50 originally came from the temperate Europeo-Siberian fauna, 10 from the Oriental fauna, 15 from the Ethiopian, 4 from the Neotropical, 7 being uncertain and 2 unknown.†

It should be noted, however, that there is grave room for difference of opinion regarding a number of the European species considered by him as indigenous to North America. Scolytus rugulosus, Hylastinus trifolii, Anthrenus scrophulariæ, Sitones hispidulus, Cryptorhynchus lapathi, and a number of others which might be specified for example, have undoubtedly been imported from Europe and were quite possibly originally imported.

There are obstacles in the way of the establishment and spread of species which are imported quite by accident which usually do not exist in the case of the so-called commercial importations. In many cases, entering the vessel by accident, they exist there as single individuals, and upon liberation, even should the conditions be favorable, only gravid females could perpetuate the species. Then also the majority of such specimens are liberated upon the unloading of the vessel upon the wharves. The water front of a seaport city is not a favorable place for the establishment of a species which feeds on living vegetation. Frequently, even when it is a species well fitted for acclimatization, it will have to fly or be carried for miles inland before it can find a place possible for the establishment of the species. So it happens that while foreign insects are frequently found in living condition about the wharves of our larger seaports during the summer months, almost none have succeeded in getting a foothold in the vicinity. Mr. Otto Lugger, when living in Baltimore, Md., made a collection of many species of foreign insects found upon the wharves, yet he has recorded the establishment of but a single species, viz., Aphodius erraticus, a European dung beetle, which managed to get to Druid Hill Park, where it bred in the dung of the tame deer, afterward spreading into the surrounding country and breeding in the dung of sheep and other domestic animals.

Practically, therefore, after many years of the most active commerce, the insect faunas of the immediate vicinity of the larger seaports, like New York, Boston, Philadelphia and Baltimore, have not been greatly changed by the introduction of foreign elements.

All of the household insects and true city insects are, of course, exceptions to this conclusion, and the strong flying, vigorous, and simple living dipterous insects—

* The spread of European species in Australia has been explained by the superior energy of the younger races of the Palearctic region.

† Hamilton, in his 1894 paper, raises the number of Coleoptera common to the two countries to 394, making the number of introduced species 216.

the very ones most likely to enter a loading vessel and to escape on the discharge of its cargo—will many of them find proper places for breeding. It is likely that a much larger proportion of the many species of Diptera common to Europe and North America have been brought over in this accidental manner than is the case with the Coleoptera.

But often these purely accidental species are carried inland in packing cases, into the cracks of which they may have crawled, or even in the trunks of passengers, and they may then be liberated in more favorable localities. For example, Mrs. H. G. Hubbard, after spending the summer on Prince Edward's Island, returned in the autumn to Detroit, Mich., and in unpacking her trunks her husband found two specimens of Phytonomus punctatus, a species not previously known to occur in Michigan, although found there in injurious numbers a year or so later. It is altogether likely that the imported elm leaf beetle (Galerucella luteola), an insect which enters houses for hibernating purposes, was first brought to America in this manner.

It is, however, the accidental commercial importations which theoretically stand the best chance of establishing themselves, since, in the first place, they are generally imported in or upon their natural food. In the second place, they generally occur in considerable numbers, instead of as isolated individuals, as with the more purely accidental importations; and, in the third place, they are usually carried as originally packed, far from the port of entry.

With insects brought over on plants or nursery stock the conditions could not well be much more favorable. Their supply of food is looked after with care, the host plant is soon put in the ground under the best of surroundings, and the greatest care is taken of the choice importation. Upon or in importations of this kind are carried Coccidæ in all stages of growth, and often, fortunately, their inclosed parasites, the eggs of Aphididæ, the larvæ of wood boring Coleoptera, the eggs of many other insects, the cocoons of small Lepidoptera, and probably even in rare cases the larvæ of Lepidoptera, since it now seems likely that Euproctis chrysorrhœa was imported into Massachusetts on nursery stock in its larval hibernacula. The Coccidæ, however, are most abundantly carried in this way. Under natural conditions these insects have usually a rather restricted distribution, but by means of this commercial distribution many of them have become of almost world-wide range, and the end will certainly not be reached until every country possesses every species of scale insect which can possibly live in its climate. A few instances drawn from a recent paper by Mr. Cockerell will illustrate this fact:

Diaspis amygdali, or lanatus, was described from Australia in 1889. To-day we know it from Australia, Ceylon, Hong-Kong, Japan, several localities in the United States, Jamaica, San Domingo, Grand Cayman, Barbados, Martinique, Trinidad, and Cape Colony.

Aulacaspis rosæ was described from Europe, but is now found also in the United States, Australia, New Zealand, the Sandwich Islands, China and Jamaica.

Chionaspis citri was described from Louisiana and Cuba in 1883 and is now known from Trinidad, Antigua, Demerara, Bermuda, Mexico, Tonga, New Zealand and Australia.

Howardia biclavis was described in 1883 from specimens on hothouse plants in Washington, D. C. Now it is known out of doors from Trinidad, Mexico, Tahiti, Sandwich Islands and Ceylon.

Lecanium oleæ is found in Europe, the United States, the West Indies, Mexico, Sandwich Islands, New Zealand, Australia and Cape Colony.

The hymenopterous parasites of the Coccidæ by virtue of their mode of life, have spread almost equally with their hosts by means of this commercial transportation. I have been able to show recently that by this means a number of species of the Chalcidid subfamilies Aphelininæ and Encyrtinæ have, in comparatively recent years, become cosmopolites. For example:

Aspidiotiphagus citrinus, originally described from California in 1891, is now found in many other portions of the United States, in the West Indies, Italy, Austria, Ceylon, China, Formosa, Japan, Cape Colony, Queensland, South Australia and Hawaii. Practically the same remarkable distribution is followed by Prospalta aurantii, Aphelinus mytilaspidis, A. diaspidis and A. fuscipennis, while the remarkable and system-breaking Encyrtine, Arrhenophagus chionaspidis, described by Aurivillius from Swedish specimens in 1888, has since been found in Austria, Italy, several portions of the United States, Ceylon, Japan, Formosa, and China.

Only second to the Coccidæ in the facility with which they are transported in this way are the Aphididæ. These insects, however, are fragile, soft bodied and unprotected. They are readily carried, however, in the winter egg condition, and many species are rapidly becoming cosmopolitan. They have not been studied, however, elsewhere than in Europe and the United States, and the extent to which this commercial distribution has been carried can only be surmised. A suggestion of this extent, however, occurred to me when within the past few weeks specimens of Aphelinus mali, a common parasite of Aphididæ in Europe and North America, were received from such a comparatively out-of-the-way corner of the world as Passaruan, Java.

Other still smaller and still less studied insects are undoubtedly carried by this method of transportation, as the recently discovered identity of certain North American Thysanoptera with those of Sweden and Russia would seem to show. The small plant-feeding mites of the family Phytoptidæ are particularly subject to this form of commercial distribution, and when they are fully studied, it will doubtless be found that many forms have become subcosmopolitan.

Of larger insects, nearly all of the wood-boring beetles common to Europe and the United States have probably been brought over in this way, Zeuzera pyrina, the large wood-boring cossid moth, also probably came over on living plants; and, as I have just stated, the newly imported brown tail moth, Euproctis chrysorrhœa, was probably at Boston with nursery stock.

Careful observations on the insects transported with this class of merchandise have never been made, except possibly at the port of San Francisco. At this port the State Board of Horticulture has established under State laws a quarantine for all incoming plants and fruit. The entomologist and quarantine officer, Mr. Alexander Craw, has entire jurisdiction over such articles consigned to points within the State, and examines, destroys and fumigates at his discretion. He has not, however, in his reports given us complete lists of the insects collected in this work, although I understand from persons who have visited his office that he has preserved collections of the more important species from an economic standpoint. The vessels examined have, almost without exception, come from Pacific ports, and the difficulty of naming insect material thus received would be very great. It is this fact which has probably hitherto prevented the publication of a general list. A list of the scale insects, however, has been published.*

Between July 2, 1894, and August 29, 1896, Mr. Craw inspected 232 vessels carrying plants or other articles liable to be infested with living insects and consigned to California individuals or firms. One hundred and twenty-two lots he found clean and passed; 40 lots he admitted after fumigation; 20 lots he destroyed and 78 lots he destroyed in part. One lot, consisting of 1,000 boxes of apples, he sent back on the refusal of the owner to allow them to be fumigated.

Living plants and nursery stock afford, then, perhaps, the most certain means for the accidental transmission and subsequent establishment of many kinds of insects. Commerce in objects of this class is rapidly increasing, and has already assumed considerable proportions, the imports into the United States alone in the fiscal year ending June 30, 1896, having reached a value of nearly $1,000,000, while the previous year they amounted to something over $900,000.

No great elaboration will be needed concerning the importation of foreign insects upon fruits, fresh and dry, other dry food stuffs, cloths, lumber or domestic animals. Fruits were imported into the United States in the fiscal year 1895-96 to the value of nearly $20,000,000, and, unquestionably, upon imported fruits are carried many insects. The opportunities for the establishment of species coming with fresh fruit, however, are obviously slight as compared with those which come on living plants or in dried foodstuffs, and, as a matter of fact, it appears that already nearly all of the dried food insects have become cosmopolitan. The same may be said of the insects which affect domestic animals. The forms which are truly parasitic in the larval stage have most of them been carried everywhere, while the other forms which attack domestic animals only as adults have some of them been carried far and wide. As an example, we may recall the European Hæmatobia serrata, which was brought to New Jersey probably in 1885, and which has spread over the entire country from Maine to California.

The fact that insects may be, and doubtless are, transmitted in the material used in packing heavy or delicate merchandise must not be overlooked. We have already shown that dangerous weeds have been transmitted in this way, and when the material is hay or straw the danger of importing certain injurious insects becomes great. Cecidomyia destructor, the well known Hessian fly, is supposed to have first been brought to the United States from Europe in straw bedding on troop vessels during the war of the revolution, and to have recently been carried from Europe to New Zealand in the straw packing of merchandise. Laws recently proposed in New Zealand, Australia and Cape Colony provide that such straw or hay packing shall be burned immediately the case is opened. Dr. H. Loew, in his well known paper, "Ueber die Dipteren-fauna des Bernsteins," has shown that several of the species of the genera Oscinis and Chlorops have gained a wide distribution through commerce, and this probably happened through their occurrence in hay or straw used as packing, since they live in the stems of grains and grasses. Dr. Loew, by the way, considered the Diptera, by virtue of the simple conditions required for their existence, to be peculiarly susceptible to commercial and accidental distribution, and was inclined to believe that the majority of the many species common to Europe and North America have been imported into the latter country. He understood, however, the existence of a circumpolar fauna, and wrote wisely and learnedly about the common ancestry of what he called analogous species. Whatever may be the cause, the Diptera seem fitted in the individual to withstand widely differing environmental conditions. The group as a whole has apparently little faunistic value either along broad lines or in a more restricted way. There are comparatively fewer characteristic genera in the main faunal regions of the world than in other groups of animals, and in our own country there are comparatively few species of restricted distribution. Very many individual species range through the Lower and Upper Austral, through the Transition and into the Boreal regions.

Aside from the Diptera, grains and grasses all over the world are subject to the attacks of a host of insects of all kinds, many of which hibernate on or within the stems, so that the proposed legal provisions of the English colonies mentioned are by no means unwise. The substitution of the wood material known as "excelsior," the use of which is becoming so common in this country, or of some other packing material, will shortly do away with a large share of this danger.

There are, of course, other less important methods by which insects may be transported, such as in earth or damp moss about the roots of plants and in sand used for ballast. These methods, however, are not very important as a rule, although it is stated that the destructive chigoe (Sarcopsylla penetrans) was carried in ballast in 1872 on a vessel from Rio Janeiro to the coast of Guinea, where it has established itself most perfectly, having been found two hundred miles inland by Stanley.†

† Die Umschau, July 17, 1897, p. 523.

Aluminum is now used in making clock hands, for which it is an ideal material. The pointers of great clocks were formerly made of soft wood. For these were substituted pointers made of thin sheets of copper, a pointer being composed of two strips, which were cupped or hollowed, and then brought together edge to edge, with the rounded sides out, thus giving rigidity as well as lightness. Aluminum pointers for big clocks are made in this way, but they are far lighter and easier to balance. It is not unusual on large clocks in windows and elsewhere to see projecting from the base of the long pointer and in line with it a rod with a ball at the end, this rod being perhaps a third as long as the big pointer. This rod and ball are a counterweight for the big pointer, which, without a counterweight, would, in its movement around the dial, wear unevenly upon the arbor or shaft which carries it. On great clocks, and often on big clocks indoors, this counterpoise is placed inside the dial, out of sight, on the arbor. The heavier the pointer, the greater the weight required in the counterpoise; the greater the weight, the more friction on the arbor; and the more friction, the greater power required to drive the clock. By the use of aluminum pointers these drawbacks are reduced to a minimum.

THE BRITISH ASSOCIATION—ADDRESS IN ANTHROPOLOGY.

The address in Section H was delivered by Prof. Sir W. Turner, D.Sc., F.R.S. L. and E., who selected as the subject:

Some Distinctive Characters of Human Structure.

When we look at man and contrast his form and appearance with other vertebrate creatures, the first thing probably to strike us is his capability of assuming an attitude which we distinguish by the distinctive term "erect." In this position the head is balanced on the summit of the spine, the lower limbs are elongated into two columns of support for standing on two feet, or for walking, so that man's body is perpendicular to the surface on which he stands or moves, and his mode of progressing is bipedal. As a consequence of this, two of his limbs—the arms—are liberated from locomotor functions; they acquire great freedom and range of movement at the shoulder joint, as well as considerable movement at the elbow and between the two bones of the forearm; the hands also are modified to serve as organs of prehension, which minister to the purposes of his higher intelligence. The erect position constitutes a striking contrast to the attitude assumed by fish, amphibia, and reptiles when at rest or moving, in which vertebrates the body is horizontal, and more or less parallel to the surface on which they move. Birds, although far removed from the erect attitude, yet show a closer approximation to it than the lower vertebrates or even the quadrupedal mammals. But of all vertebrates, those which most nearly approximate to man in the position assumed by the body when standing and walking are the higher apes. The various adaptations of structure in the trunk, limbs, head, and brain which conduce to give man this characteristic attitude are essential parts of his bodily organization, and constitute the structural test which one employs in answering the question whether a particular organism is, or is not, human. These adaptations of parts are not mere random arrangements, made at haphazard and without a common purpose; but are correlated and harmonized so as to produce a being capable of taking a distinctive position in the universe, superior to that which any other organism can possibly assume. If we could imagine a fish, a reptile, or a quadruped to be provided with as highly developed a brain as man possesses, the horizontal attitude of these animals would effectually impede its full and proper use, so that it would be of but little advantage to them. It is essential, therefore, for the discharge of the higher faculties of man, that the human brain should be conjoined with the erect attitude of the body. The passage of a vertebrate organism from the horizontal position, say of a fish, in which the back, with its contained spinal column, is uppermost, and the head is in front, to the vertical or erect position of a man, in which the back, with its contained spinal column, is behind, and the head is uppermost, may be taken as expressing the full range and limit of evolution, so far as the attitude is concerned, of which such an organism is capable. Any further revolution of the body, as in the backward direction, would throw the back downward, the head backward, and would constitute a degradation. It would not be an advance in the adaptation of structure to the duties to be discharged, but rather an approach to the relation of parts existing so generally in invertebrate organisms.

ANATOMY OF MAN AND THE LOWER ANIMALS.

By the publication in 1859 of Darwin's ever-memorable treatise "On the Origin of Species by Means of Natural Selection," an enormous impulse was given to the study of the anatomy of man in comparison with the lower animals, more especially with the apes. By many anatomists the study was pursued with the view of pointing out the resemblances in structure between men and apes; by a more limited number to show wherein they did not correspond. I well remember a course of lectures on the comparative characters of man delivered 35 years ago by my old master, Prof. John Goodsir, in which, when speaking of the hand of man and apes, he dwelt upon sundry features of difference between them. The human hand, he said, is the only one which possesses a thumb capable of a free and complete movement of opposition. It may be hollowed into a cup and it can grasp a sphere. It is an instrument of manipulation co-extensive with human activity. The ape's hand is an imperfect hand, with a short and feeble thumb, and with other clearly defined points of difference and inferiority to that of man. It can embrace a cylinder as the branch of a tree, and is principally subservient to the arboreal habits of the animal. Its fingers grasp the cylinder in a series of spirals. Here, then, is an important difference in the manipulative arrangements of the two hands, the advantage being with the hand of man, in regard to the greater variety of movement and adaptability, to co-ordinate it with his reasoning faculties. As showing the acuteness of perception of Goodsir and his complete recognition of a fundamental feature of the human hand, he also dwells on the hand being able to form a circle around a sphere, so as to grasp it on every side, and to touch it with every part of itself, while it can also securely hold objects that possess plane or concave surfaces. If we compare the new born infant with the young of vertebrates generally, we find a striking difference in its capability of immediately assuming the characteristic attitude of the species. A fish takes its natural posture and moves freely in its element as soon as it is hatched. A chicken can stand and walk when it is liberated from the egg, though, from its

wings not being developed, it is not at once able to fly. A lamb or calf can assume the quadrupedal position in a few minutes after birth. But, as we all know, the infant is the most helpless of all young vertebrates, and is months before it can stand on two feet and move freely on them. During the period of transition, from the stage of absolute dependence on others to the acquisition of the power of bipedal progression, important modifications in the structural arrangements both of the spine and lower limbs have to take place. At the time of birth the infant's spinal column exhibits only two curves; one, corresponding to the true vertebræ, extends from the upper end of the neck to the lowest lumbar vertebra, and the concavity of its curve is directed forward; the other and shorter corresponds to the sacro-coccygeal region, and also has its concavity directed forward. In the number and character of the curves, the new-born infant differs materially from the adult man, in whose spine, instead of one continuous curve from the neck to the sacrum, there are alternating curves, one convex forward in the region of the neck, succeeded by one concave forward in the region of the chest vertebræ, which again is succeeded by a marked convexity forward in the vertebræ of the loins. The sacro-coccygeal region continues to retain the forward concavity of the new-born child. The formation and preservation of this alternating series of curves is associated with the assumption of the erect attitude, and the development of the lumbar convexity is correlated with the straightening of the lower limbs when the child begins to walk.

THE ERECT ATTITUDE.

It has sometimes been assumed that the acquisition of the erect attitude by the young child is due to the fostering care of the mother or nurse; that it is a matter of training, encouragement, and education, without which the child would not raise itself upon its feet. I cannot, however, agree with this opinion. If one could conceive an infant so circumstanced that, though duly provided with food fitted for its nutrition and growth, it should never receive any aid or instruction in its mode of progression, there can, I think, be little doubt that when it had gained sufficient strength it would of itself acquire the erect attitude. The greater growth in length of the lower limbs, as compared with the upper, would render it inconvenient to retain the creeping or the quadrupedal position. We cannot lose sight of the important influence which, altogether independent of education, is exercised by parents on their offspring. The transmission of hereditary qualities, through the germ from which each individual organism is derived, is one of the fundamental and most striking properties of the germ plasm. Characters and peculiarities which appertain not only to the family of which the individual is a member, but also to the species to which he belongs, are conveyed through it from one generation to another. Hence, as the capability of assuming the erect attitude and of thus standing and moving on two feet have been attributes of the human form from its beginning, there can be little doubt that this power is potential in the human organism at the time of birth, and only requires a further development of the nervous and muscular systems to become a reality, without the aid of any special training. The spinal column in the region of the true vertebræ consists of numerous bones jointed together, and with disks of soft fiber cartilage interposed between and connecting the bodies of adjoining vertebræ with each other. It is to their presence that the spinal column owes its flexibility and elasticity. These disks are larger and thicker in the region of the loins, where the lumbar convexity is situated, than in other parts of the column, and there can be no doubt that the acquisition of this convexity is intimately associated with the presence of these disks. It is a matter for observation and consideration to what extent the bodies of the vertebræ contribute to the production of this curve. A few years ago Prof. Cunningham, of Dublin, and I undertook much about the same time researches into the form and dimensions of the bodies of these bones. Our observations were made independently of each other and on two different series of skeletons, and as we arrived at practically the same conclusions, we may, I think, infer that, in their main features at least, these conclusions are correct.

THE SPINAL COLUMN.

The method followed in the investigation was to measure the diameter from above downward of the body of each of the five lumbar vertebræ, both in front and behind. If the upper and lower surfaces of the bodies of the vertebræ were parallel to each other, it is obvious that, so far as they are concerned, the column formed by them would be straight, as in the case in a column built of hewn stones possessing similar parallel surfaces. But if the surfaces are not parallel, the body of the vertebra is wedge shaped; should the front of the collective series of bones have a greater vertical diameter than the back, it is equally obvious that the column would not be straight, but curved, and with the convexity forward. From the examination of a considerable number of spinal columns of Europeans, we found that, although the vertical diameter of the bodies of the two highest vertebræ was greater behind than in front, in the two lowest the anterior vertical diameter so greatly preponderated over the posterior that the anterior vertical diameter of the bodies of the entire series of lumbar vertebræ in each spine was collectively greater than the corresponding diameter of the posterior surface. In twelve European skeletons I observed that the mean difference was between 5 mm. and 6 mm. in favor of the anterior surface. If we are to regard the collective vertical diameter anteriorly of the five bones as equal to 100, the same diameter posteriorly is only equal to 96, which may be regarded as the lumbar index in Europeans. Dr. Cunningham obtained a similar index from the examination of a much larger number of European skeletons, and he further showed that in women the lumbar convexity forward is more pronounced than in men. It follows, therefore, from these observations that when the broad end of the wedge shaped bodies is in front, the bones themselves would, by their form, give a forward convexity to the spine in the lumbar region. But a similar wedge shaped form is also possessed by the lower intervertebral disks in this region, and especially by that interposed between the last lumbar vertebra and the sacrum. Hence it follows that both vertebral bodies and intervertebral disks contribute in the white races to the production of the lumbar convexity. When we pass to the examination of the corresponding region in the spines of those races of men that we are accustomed to call lower races, we find a remarkable and important difference. Let us take, as a characteristic example of a lower race, the aborigines of Australia. In their skeletons our observations have proved that the vertical diameter of the bodies of the five lumbar vertebræ was collectively deeper behind than in front. In my series of skeletons the mean difference was between 6 mm. and 7 mm. in favor of the posterior surface, so that they possessed the opposite condition to that which prevails in Europeans. Hence if the spine had been constructed of vertebræ only, instead of a lumbar convexity, the column would have possessed a forward concavity in that region. For this character, as shown in the skeleton only, I have suggested the descriptive term "Koilorachic." We know, however, that elastic disks are intercalated between the bodies of the osseous vertebræ in the black races as well as in Europeans. It is necessary, therefore, to examine their spinal columns, when the intervertebral disks are in position, in order to obtain a proper conception of the character of the curve in the living man.

(To be continued.)

MERCURY COLUMNS.

AN accurate method of measuring the intensity of fluid or gaseous pressure is indispensable to engineers and physicists, and many forms of apparatus have been devised to meet the requirements of practical use. The Bourdon gage is most commonly used in connection with steam boilers, because it is compact and durable and is sufficiently accurate for all ordinary purposes. Gages in use about steam plants should be periodically tested, however, by comparison with some standard manometer of known accuracy, and as our regular work of boiler inspection requires us to test many thousands of gages each year, we have given considerable thought to the design and construction of standard apparatus for performing such tests with satisfactory precision. Many experimenters in physics have used manometers in which the pressure is measured by the change in volume that is experienced by a given mass of gas inclosed in a graduated glass tube of known capacity.

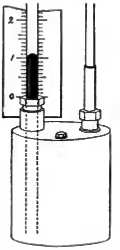

FIG. 1.—A DETAIL OF A MERCURY GAGE.

Nitrogen gas is frequently used for this purpose, because its compressibility has been studied with great care by Amagat. This method of measuring pressures has its advantages, but it has also the marked disadvantage of requiring the observer to note the temperature very accurately, because the volume of the test gas varies with the temperature so notably that a small thermometric error may introduce an error in the reading of the instrument which would be quite inadmissible. In our judgment, the gas manometer is not a satisfactory device for everyday testing purposes. It is much more satisfactory to compare the gage directly with a mercury column, and this is the method that we use in standardizing the test gages that are supplied to our inspectors. The apparatus consists in a pump, by which the gage can be subjected to a water pressure, and a long, vertical glass tube, in which mercury rises to measure the pressure. The mercury is contained in an iron reservoir, as shown in Fig. 1. Two tubes pass out through the top of this reservoir, one of which (shown on the right) transmits the water pressure from the gage table to the mercury reservoir, while the other is the glass tube already referred to, into which the mercury rises. The apparatus is so simple that it hardly needs further explanation, except on the one point of fixing the graduation marks on the scale. This appears to be simple enough, but as we have frequent letters asking how it is done, we shall explain the process of graduation in some detail. Referring to Fig. 2, let us suppose that the diagram on the left represents a little cubical vessel, one inch high, wide and deep, filled with mercury. The weight of the mercury all comes on the bottom of this vessel. Now a cubic inch of mercury weighs about 0·49 of a pound, and hence the pressure on the one square inch that forms the bottom of this little vessel would be 0·49 of a pound. Suppose, now, that we had a similar vessel which is one inch square at the bottom, as before, but which is three inches high, as shown in the middle diagram. This vessel would contain three cubic inches of mercury, and the pressure on the one square inch of its bottom side would be $3 \times 0·49 = 1·47$ pounds. In the same way, if we had a vessel one inch square and (say) 120 inches high, the pressure against the square inch at the bottom would be $120 \times 0·49 = 58·80$ pounds, and so on for any other height. Now let us consider the right hand diagram in Fig. 2. Here the vessel is supposed to be only half an inch square; but it is plain that the pressure per square inch on the bottom of the vessel would be just the same as in the middle diagram, because, although there is only one-quarter as much mercury as before, there is also one-quarter as much area on the bottom of the vessel for it to rest upon; and hence the pressure per unit of area, that is, the pressure per square inch, will be just the same in either case. It will be evident, by this same process of reasoning, that the shape of the cross section of the vessel or tube has nothing to do with the intensity of the pressure. In a word, the pressure exerted by the mercury depends upon nothing but the height of the column; and we can calculate it, in any case, just as though the column were an inch square, as we did in connection with the middle diagram of Fig. 2. In carrying out this idea in the actual work of graduation certain precautions must be observed. For example, we must make sure that the mercury is clean and pure, and that it is not contaminated with tin, or zinc, or lead, or any other substance which may affect its specific gravity. If these substances are present in appreciable amount, the weight of a cubic inch of the mercury will not be the same as the values given in the standard tables, and hence we must either purify the mercury before using it or we must weigh a cubic inch of it very accurately, so as to know by how much it departs from the standard density given in the books. It will be seen that the pressure exerted by a mercury column ten feet high will be one thing in one part of the earth and another thing in some other part. The difference is not very great, it is true, and yet it ought to be taken into account in designing mercury gages for accurate testing purposes. The expression "pounds per square inch" is illogical and meaningless, in the last analysis, although it serves well enough for the ordinary rough work of steam engineering practice. We might speak with accuracy of the number of "poundals per square inch," but this would take us too far away from the conventions of engineering practice; and as a sort of concession to the ordinary, though incorrect, use of the word "pound" as a force, we may adopt the following provisional definition of the word "pound," as it occurs in the expression "pounds per square inch." Definition:

A "pound," in estimating the pressure produced by a column of mercury, is understood to be the force with which the earth attracts a standard avoirdupois pound weight at sea level in the latitude of Washington.

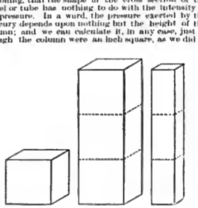

FIG. 2.—ILLUSTRATING THE PRESSURE DUE TO A COLUMN OF MERCURY.

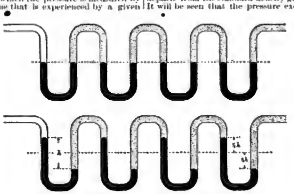

FIG. 3.—ILLUSTRATING THE "SIPHON GAGE."

With this much admitted we are ready to proceed to the problem of graduating our column. It has been found, by careful experiment, that a cubic inch of pure mercury, at 32° Fahr., has a mass of 0·49117 of a pound. Hence, according to the foregoing definition, a column of mercury one inch high gives a pressure of 0·49117 when at a temperature of 32° Fahr. at sea level in the latitude of Washington. If this one inch column of mercury were to be carried toward the equator, or up a hill or a mountain, it would produce a less pressure than this, because the earth would attract it less forcibly in those places. So, too, the pressure produced by a one inch column would be less than 0·49117 pound, if the mercury were warmer than 32° Fahr., because mercury expands upon being heated, and hence it weighs less per cubic inch at higher temperatures. To find the actual pressure produced by a one inch column of mercury, as it stands in the column in our Hartford office, we must therefore take into account three things: (1) the temperature of our column, (2) the difference in latitude between Hartford and Washington, and (3) the elevation of our office above mean sea level. The latitude of our Hartford office being 41° 46', and the temperature of the mercury column being always very near to 70°, we see from the table that it is necessary to allow 2·043 inches for each pound of pressure desired. The best way to carry out the actual work of graduation is probably to lay off, first, the positions of the marks for 10 pounds, 20 pounds, 30 pounds, etc., allowing 20·43 inches for each 10 pounds. Then the intermediate one pound divisions can be filled in upon the skeleton so laid down with great accuracy. The scale itself is best made of well seasoned and varnished pine wood, since the coefficient of expansion of pine is so small that a scale 45 feet long will vary in length by less than the thousandth part of an inch for each Fahrenheit degree of change in its temperature. The scale, when once made and graduated, is to be so adjusted that the mercury column reads accurately zero, when there is no pressure on the testing apparatus. The reading of any mercury gage that is open to the air at one end merely gives the excess of the observed pressure above that of the atmosphere. If the absolute pressure is desired, the reading of the barometer must be noted at the same time, and the atmospheric pressure, so determined, must be added to the reading of the column. When high pressures are to be determined, it is often inconvenient to read the ordinary mercury column, since the top of it is then far above the floor of the testing room. To remedy this difficulty various modifications of the column have been proposed. One of the earliest plans proposed, we believe, by Fahrenheit, is that suggested in Fig. 3. Instead of a single long column we have here a considerable number of shorter ones arranged in U-shaped tubes. The various spaces between the successive lengths of mercury are filled with water or glycerine or some other practically incompressible fluid, which serves to transmit the pressure from each body of mercury to the next. The position of the mercury when in equilibrium under atmospheric pressure at each end is shown in the upper part of the figure. When pressure is applied, the system assumes the configuration shown in the lower diagram, each U of mercury rising in one leg and falling in the other. The head due to each body of mercury is indicated on the left by the letter h, and as will be seen it is equal to double the amount by which the level has risen or fallen in any one leg. The total head of mercury in the entire apparatus is found by multiplying h by the number of U tubes that are present; and a considerable head of mercury can therefore be realized, without the necessity of extending the column to an inconvenient height. The foll head, h, of the mercury in the U tubes cannot be taken in computing the pressure produced by the system, since each of the columns, h, is partially balanced by an equal column of water or glycerine, and allowance must be made for this fact.—The Locomotive.

The longest tunnels in the world are the following, says the Engineering and Mining Journal: Gothard, 14,900 m.; Mount Cenis, 12,220 m.; Arlberg, 10,270 m.; Ronco (Italy), 8,297 m.; Ceylon, 8,000 m.; Hoosac, 7,640 m.; Severn, 7,250 m.; Marioropoli (Italy), 6,480 m.; Sutro (United States), 6,000 m.; Sandbridge (England), 4,970 m.; St. Lawrence (Canada), 4,570 m.

PAVEMENTS FOR CITY STREETS.

THE street commissioner of St. Louis has issued a very instructive pamphlet illustrated by half-tone engravings, showing the condition of the streets of that city and the methods adopted for paving it. This pamphlet is accompanied with excellent sectional views, showing the method of construction adopted in laying the various forms of pavement. These sections are particularly instructive, as St. Louis includes not only streets where traffic is heavy, but avenues, boulevards, and park roads where the travel is mostly light. By kind permission of the street com[illegible]ssioner, Mr. Abram M. Milner, we are enabled to r[illegible] these sectional views. The report contains ad[illegible]fications which are worthy of adoption [illegible] and though the estimated cost of mat[illegible] is based on the local price in St. Louis [illegible]s are very valuable in estimating in ot[illegible]

The cost of street construction is estimated to be as follows:

STREET CONSTRUCTION.

Estimated cost of materials used in street construction:

Street complete, paved with granite	$30.00 per square.
Street complete, paved with brick	18.00 " "
Street complete, paved with rock asphaltum	$25.00 per square.
Street complete, paved with Trinidad L asphaltum	30.00 " "
Street complete, paved with Telford	10.00 " "

Cost of street paving material:

Preparing roadway	$0.30 per cubic yard.
Telford	4.00 " square.
Macadam	4.00 " square.
Concrete, 6 in. deep	$7.00 per square.
Cinders	2.00 " "
Sand	2.00 " "
Gravel	7.00 " "
Curbing, 6 in. granite, 16 in. deep	1.00 " linear foot.
Curbing, 8 in. oolitic, 16 in. deep	.80 " " "
Combination curb and gutter	$0.90 per linear foot.
Rolling	8.25 " day.
Vitrified brick	11.00 " square.
Granite blocks	25.00 " "
Asphaltum, complete	30.00 " "

Curb stones not to be less than 4 ft. 6 in. long.

Size of granite blocks:

Not less than 9 in. nor more than 12 in. long.
" " " 3½ " " " " 4½ " wide.
" " " 7½ " " " " 8½ " deep.

BRICK PAVEMENT WITH STONE CURB.

TELFORD PAVEMENT WITH CONCRETE GUTTERS.

Size of vitrified brick;

Not less than 8 in.	nor more than	9 in.	long.
" " " 2½ "	" " "	4 "	wide.
" " " 4 "	" " "	4½ "	deep.

Size of vitrified blocks;

Not less than 9 in.	nor more than	12 in.	long.
" " " 3½ "	" " "	4½ "	wide.
" " " 5 "	" " "	6 "	deep.

Cost of granitoid sidewalk:

Single thick, 8 in. cinders, 3½ in. lower course concrete, ½ in. wearing surface .... 14½ cents per square foot.

Cost of a 60 ft. street, 36 ft. roadway, improved with:

Granite..........................	$8.00 per front ft.
Brick	4.50 " " "
Asphaltum.......................	7.00 " " "
Telford...........................	2.75 " " "

Alleys:

15 ft. granite alley............	$2.25 per front ft.
20 " " "	3.00 " " "
15 " brick "	1.40 " " "
20 " " "	1.75 " " "
15 " limestone "	1.00 " " "
20 " " "	1.30 " " "

and of such length as may be directed by the street commissioner.

COLORING.

The wearing surface of the sidewalk pavement, when required, shall be mixed with such color or colors as the street commissioner may direct.

PREPARING THE BED FOR THE SIDEWALK PAVEMENT.

The sidewalks shall be excavated and shaped to the proper depth and grade as directed by the street commissioner, and all the refuse material therefrom shall belong to the contractor and shall be promptly removed from the line of work.

ORDINARY SINGLE FLAGGING.

After the shaping is done, a foundation of cinders not less than eight inches thick shall be placed upon the subgrade, which shall be well consolidated by ramming to an even surface, and which shall be moistened just before the concrete is placed thereon.

After the subfoundation has been finished the artificial stone flagging shall be laid in a good, workmanlike manner.

The same to consist of two parts: First—A bottom course, to be three and one half inches in depth.

Second—A finishing or wearing course, to be one-half inch in depth.

The bottom course shall be composed of crushed

shall have a straight face, fine pean hammer finish on the side toward the roadway for the full depth of the stone, and pitched to line and rough pointed on the side toward the sidewalk, to a depth of six inches from top of curb, and shall have close end joints to the full depth of the stone, and no stone shall be less than four and one half feet long, nor less than six inches thick, nor less than sixteen inches deep. The curbing shall be set on concrete, six inches deep and twelve inches wide, and backed with concrete six inches wide and ten inches deep, or six inches below top of curbing. The quality of the curb shall be equal in material, dimensions and finish to the sample in the street commissioner's office.

Care must be taken not to disturb or break the sidewalk pavement more than necessary, and in all cases, unless otherwise directed, the sidewalk pavement, whenever broken, shall be fully restored.

Whenever the excavation of the roadbed develops too great a width of joint between the old curbing left in position, or openings in the area walls, such joints or openings shall be filled with cement mortar, the mortar being made of one part of cement to one part of sand, or, if necessary, with concrete, as may be determined by the street commissioner.

CONCRETE FOUNDATION.

Upon the roadbed a foundation of hydraulic cement concrete shall be laid to a uniform depth of eight

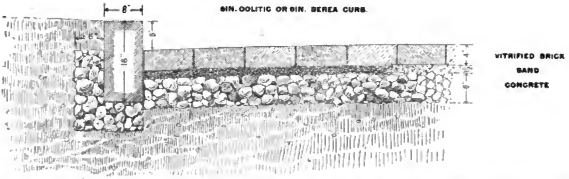
BRICK PAVEMENT

6 IN. OOLITIC OR 6 IN. SEREA CURB.



The specifications for granitoid sidewalk are as follows.

CEMENT.

All cement shall be fine ground. Eighty five per cent. shall pass through a sieve having ten thousand meshes to the square inch.

All cement shall be capable of withstanding a tensile strain of five hundred pounds per square inch of section, when mixed neat, made into briquettes and exposed twenty-four hours in air and six days under water.

All cement shall be capable of withstanding a tensile strain of two hundred pounds per square inch of section, when mixed in the proportion of three parts sand to one part cement, and exposed twenty-four hours in air and twenty-eight days under water.

All cement shall be put up in well made barrels, and all short weight or damaged barrels will be rejected. Cement without manufacturer's brand and certificate will be rejected without test.

All cement will be subjected to tests for soundness or permanence of volume. All cement for use on the works shall be kept under cover, thoroughly protected from moisture, raised from the ground, by blocking or otherwise, and dry until used. The contractor shall keep in storage a quantity of accepted cement sufficient to insure the uninterrupted progress of the work.

All cement furnished will be subjected to tests of such character as the street commissioner shall determine, and any cement which, in the opinion of the street commissioner, is unsuitable for the work herein specified, will be rejected.

METAL PARTING STRIPS.

The contractor will be required to use metal parting strips, four inches deep, one fourth of an inch wide granite and Portland cement, which shall be mixed in the proportion of one part of cement and three parts of crushed granite.

The crushed granite shall consist of irregular, sharp edged pieces, so broken that each piece will pass through a three-fourths of an inch ring in all its diameters, and which shall be entirely free from dust or dirt.

The crushed granite and the cement in the above mentioned proportions shall first be mixed dry, then sufficient clean water shall be slowly added by sprinkling while the material is constantly and carefully stirred and worked up, and said stirring and mixing shall be continued until the whole is thoroughly mixed.

This mass shall be spread upon the subfoundation and shall be rammed until all the interstices are thoroughly filled with cement.

Particular care must be taken that the bottom course is well rammed and consolidated along the outer edges.

After the bottom course is completed, the finishing or wearing course shall be added. This course to consist of a stiff mortar, composed of equal parts of Portland cement and the sharp screenings of the crushed granite, free from loamy or earthy substances, and to be laid to a depth of one-half of an inch and to be carefully smoothed to an even surface, which, after the first setting takes place, must not be disturbed by additional rubbing.

When the pavement is completed, it must be covered for three days and be kept moist by sprinkling.

GRANITE STREET CONSTRUCTION.

GRANITE CURBING.

The specifications are as follows: All curbstones shall be of the best quality of granite. The curbing

inches. It shall be prepared and applied as herein specified.

SAND.

The sand used in the mortar shall be clean, coarse, screened, Mississippi River channel sand.

CEMENT.

The cement shall be hydraulic cement, equal in all respects to the best Utica or Louisville cement. It shall be newly made, fine ground, ninety per cent. shall pass through a sieve having twenty-five hundred meshes to the square inch, and capable of withstanding a tensile strain of one hundred and fifty pounds per square inch of section when mixed pure, made into briquettes and exposed twenty-four hours in air and six days in water.

All cement shall be in original packages and branded with the name of the manufacturer. Samples for testing shall be furnished in such manner and at such times as may be required. All barrels or packages accepted shall be marked, and the contractor shall carefully preserve these marks and not allow them to be imitated. The cement shall be kept under cover and dry until used, and any cement exposed to the weather after testing shall not be used. Cement may be reinspected at any time when the street commissioner shall so direct, and, if not found to be of proper quality, it shall be rejected. All rejected cement shall be at once removed from the work.

BROKEN STONE OR BROKEN VITRIFIED BRICK.

The material for the body of the concrete shall be composed of limestone or vitrified brick, broken so as to pass through a two inch ring in its largest dimensions. The material shall be free from all dust or dirt. Any stone or broken vitrified brick that is dirty or in-

ferior in quality, or not of proper size, will be rejected, and must be immediately removed from the work.

CONCRETE.

All concrete shall be made of one part of cement, two parts of sand and four parts of broken stone or brick, by volume, all to be of the quality and kind hereinbefore specified.

MORTAR.

The mortar shall be composed of one part of cement and two parts of sand, by volume. The sand and cement to be thoroughly mixed dry in proper boxes, after which a sufficient quantity of water shall be added to produce a mortar of proper consistency and the whole thoroughly mixed.

The mortar shall be mixed fresh for the work in hand, and any mortar which has begun to set shall not be used.

The mortar shall be thoroughly worked and the broken material added, and the whole mass mixed by turning not less than three times on the platform on which the concrete is made. The concrete shall be mixed on a platform prepared for that purpose.

The concrete shall be deposited in place and shall conform to the grade and cross section of the street, to be compacted so as to produce a smooth surface and a uniform distribution of the materials throughout the mass.

No walking or driving over concrete in place shall be permitted when it is setting, and it shall be allowed to set for at least twelve hours and such additional length of time as may be directed by the street commissioner before the pavement is put down. All materials used in the construction of the pavement shall be brought on to the concrete in barrows, or delivered on the concrete from the sidewalk.

PAVEMENT.

On the concrete foundation thus prepared, a bed of clean, sharp sand, free from moisture, two inches deep shall be laid. The granite blocks shall be set stone to stone and hammered tight; the end and longitudinal joints shall be as close as possible; and the longitudinal joints shall be broken so as to leave a lap of at least three inches. The course shall be set at such angles to the line of the street as may be directed.

After a certain number of courses have been set, which shall be determined by the street commissioner, or his duly authorized agent, the joints shall be swept full of sand and each course rammed with a rammer weighing not less than seventy-five pounds. The first ramming being completed, the surface shall be sanded and then wet down with a hose until the water flushes to the surface, after which the ramming shall be repeated, course by course, until the pavement is compact and solid and in conformity with the line and cross grade of the street. The pavement shall then be covered with a uniform layer of coarse, sharp sand, three-fourths of an inch deep.

PAVING BLOCKS.

The blocks shall be of good sound granite, equal in quality and dressing to sample on exhibition at the office of the street commissioner, of uniform grain and texture, free from excess of mica or feldspar. No stone which shows any appearance of disintegration, nor blocks cut from surface stones or bowlders, will be accepted. The blocks shall not be less than nine inches nor more than twelve inches long; not less than three and one-half inches nor more than four and a half inches wide; not less than seven and a half inches nor more than eight and a half inches deep, and dressed so as to approximate closely a rectangular form with opposite faces closely approximating equal areas. All questions in regard to form of block, accuracy of dressing, or quality of stone, shall be determined by the street commissioner, or his duly authorized agent.

BRICK STREET CONSTRUCTION.

OOLITIC LIMESTONE CURBING.

All curbstones shall be of the best quality of hard dark blue oolitic limestone from quarries of established reputation, free from seams or other defects. All curbing shall have close end joints to the full depth of the stone, and no stone shall be less than four and one-half feet long nor less than eight inches thick, and not less than sixteen inches deep. Each stone shall have parallel sides. The edge toward the roadway shall be rounded with a radius of one and one-half inches. The curbing shall be set on concrete six inches deep and fourteen inches wide, and backed with concrete six inches wide and ten inches deep, or six inches below top of curbing.

Curb to be dropped four inches or more at all driveways, unless otherwise ordered. The quality of the curb shall be equal to the sample in the street commissioner's office.

CONCRETE FOUNDATION.

Upon the roadbed a foundation of hydraulic cement concrete shall be laid to a uniform depth of six inches. (See Concrete Foundation in Granite Street Construction.)

VITRIFIED BRICK WEARING SURFACE.

Upon the foundation of concrete shall be laid a bed of coarse, screened sand, one and one-half inches in thickness when compacted, to serve as a bed for the bricks. Upon this base of sand a pavement of the best quality of vitrified paving brick shall be laid. The

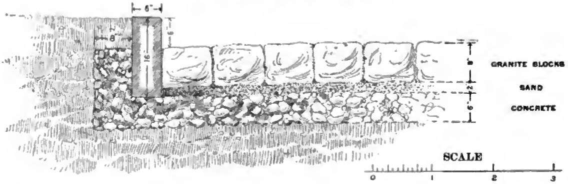
GRANITE PAVEMENT



bricks shall not be less than eight inches nor more than nine inches long, not less than two and one-half inches nor more than three and one-half inches wide, not less than four inches nor more than four and one-half inches deep, with rounded edges with a radius of three-eighths of an inch. Said brick shall be of the kind known as "repressed" brick, and shall be repressed to produce a mass free from internal flaws, cracks or laminations.

The bricks shall be free from lime or other impurities that will injuriously affect them when immersed in water, uniform in size and quality, and thoroughly burned and annealed.

All brick so distorted in burning, or with such prominent kiln marks as to produce an uneven pavement, shall be rejected.

Each bidder shall submit one hundred bricks, which shall be subjected to such physical tests as may, in the opinion of the street commissioner, be necessary to determine their quality and suitability for the work.

To secure uniformity in bricks of approved manufacture, delivered for use, the following tests shall be made:

1. They shall show a modulus of rupture in cross-breaking of not less than twenty-five hundred pounds per square inch.

2. Specimen bricks shall be placed in the machine known as a "Rattler," twenty-eight inches in diameter, making thirty revolutions per minute. The number of revolutions for a standard test shall be eighteen hundred, and if the loss of weight by abrasion or impact during such a test shall exceed thirty per cent. of the original weight of the bricks tested, then the bricks shall be rejected. An official test to be the average of two of the above tests.

No bid contemplating the use of rejected brick shall be entertained.

Samples may be submitted by manufacturers, in which case the bidder proposing to use brick of such manufacture will not be required to submit samples. The quality of the brick furnished must conform to the samples presented by the manufacturers and kept in the office of the street commissioner.

The street commissioner reserves the right to reject any and all bricks which, in his opinion, do not conform to the above specifications.

Any brick may have a proper shrinkage, but shall not differ materially in size from the accepted samples of the same make, nor shall they differ greatly in color from the natural color of the well burned brick of its class and manufacture.

No bats or broken bricks shall be used, except at the curbs, where nothing less than a half brick shall be used to break joints. The bricks to be laid in straight lines and all joints broken by a lap of at least two inches, to be set on edge on the sand as closely and compactly as possible and at right angles with the line of the curb, except at street intersections, where they are to be laid as the street commissioner may direct.

The pavement to be thoroughly rammed two or three times with a paver's rammer weighing not less than seventy-five pounds. The pavement to be surfaced up by using a long straight edge and by a thorough rolling of the pavement with a road roller weighing not less than three nor more than six tons, and when completed to conform to the true grade and cross section of the roadway.

All the joints in the pavement shall be completely filled with Portland cement grout. The cement to be of brand approved by street commissioner, to be fine ground; 85 per cent. shall pass through a sieve having 10,000 meshes to the square inch. All cement shall be capable of withstanding a tensile strain of 500 pounds per square inch of section, when mixed neat, made into briquettes and exposed 24 hours in air and 6 days under water. All cement shall be put up in well made barrels, and all short weight or damaged barrels will be rejected. Cement without manufacturer's brand and certificate will be rejected without test.

The grout shall be mixed in portable boxes in the proportion of 1 part cement to 1 part sand. The cement and sand to be thoroughly mixed together dry, then sufficient water to be added to make the grout of proper fluidity when thoroughly stirred.

The grout shall be transferred to the pavement in hand scoops, or as the street commissioner may direct, and rapidly swept into the joints of the pavement with proper brooms.

Teams, carts and wagon traffic and wheeling in barrows, except on plank, will not be allowed on the pavement for at least 7 days after the grout is applied.

The surface of the pavement, when completed, shall be covered with ½ inch of clean, coarse sand, of approved quality, which, with all dirt, shall be removed from the pavement and sewer inlets by or at the expense of the contractor at such time before the final acceptance of the work as the street commissioner may direct.

ROCK ASPHALTUM PAVEMENT.

The foundation is the same as granite or brick.

WEARING SURFACE.

Upon the base thus formed shall be placed a wearing surface as follows:

A mixture of American bituminous rock, which shall be prepared and laid on said concrete base as follows: The wearing surface shall be composed of bituminous sand rock from the Chickasaw Nation or Breckinridge County, Ky., 66⅔ to 50 per cent.; bituminous lime rock from the Buckhorn mines in the Chickasaw Nation, 33⅓ to 50 per cent. The rock of both materials shall be ground finely and thoroughly mixed and nothing shall be added to or taken from the powder obtained by grinding the bituminous rock. This pow-

der shall be heated in a suitable apparatus to a temperature of from 150° to 200° Fah.; it shall be brought to the street in suitable carts and spread with rakes to an even thickness of such depth as will insure a uniform thickness of 2 inches after having received its ultimate compression. The surface shall then be compressed by tamping and rolling, after which a small amount of hydraulic cement will be swept over it, and then it will be thoroughly compressed by a steam roller weighing not less than 5 tons.

The bituminous sand rock shall contain from 9 to 12 per cent. of pure bitumen. The bituminous lime rock shall be as nearly as possible a pure carbonate, thoroughly and evenly impregnated with asphalt having no more impurities than the standard German rock asphalt of Limmer or Vorhole, and shall contain not less than 7 per cent. and not more than 12 per cent. of bitumen, according to the richness of the bituminous sand used.

The other illustrations show a Telford pavement with vitrified brick gutter; an improved Telford pavement with granitoid curbs; a Macadam pavement with granitoid curbs, and a park road. They are model pavements, and, with the aid of the foregoing specifications, no further description seems necessary. Valuable papers on roadways and street pavements will be found in our SUPPLEMENT, Nos. 971, 828, 578, 476, 567, 843, 826, and 845.

[Continued from SUPPLEMENT, No. 1135, page 18137.]

PERPETUAL MOTION.—V.*

CARNOT'S OPINION OF PERPETUAL MOTION.

THE celebrated physicist and mathematician Carnot has given his opinion on "perpetual motion" as follows:

From what we have observed regarding friction and other passive forces, it may be inferred that perpetual motion is a thing absolutely impossible, when only such bodies are employed as are not acted on by motive power, or any heavy body; for, as these passive forces, which cannot be avoided, are constantly resisting, it is evident that the movement must continually abate; and from what has been said, it will be seen that, when

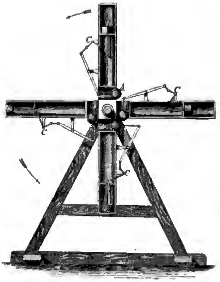

FIG. 22.

bodies are not acted on by any motive power, the sum of active force will be reduced to nothing: that is to say, that the machine will be brought to rest when the amount of activity absorbed by friction, since the commencement of the movement, will have become equal to one-half of the initial active force; and when the bodies are weights, the movement will terminate when the amount of activity absorbed by the friction equals one-half of the initial active force. Moreover, one-half of the active force existing, if all the parts of the system have a common speed, equals that which is due to the height of the point where, in the first instance of the movement, was the center of gravity above the lowest point to which it can descend.

It is easy to apply the same reasoning to constructions where springs are used, and generally to all such constructions where, abstracting from friction, the moving force, in order to bring the machine from one position to another, must consume an amount of activity as great as that which is absorbed by the resisting forces when the machine returns from the last to the previous position.

The movement will terminate still sooner, if any percussion takes place, as the sum of active force is always diminished in such cases.

It is therefore evident that one must altogether despair of producing what is called the perpetuum mobile, if it be true that all the motive powers existing in nature consist in nothing but attraction, and that it is a general property of this power to be always equal at equal distances between given bodies; that is to say, to be a function that only varies in cases where the distance of these bodies varies itself.

This opinion may be appropriately followed by that of Dr. Lardner, given in the following extract:

There is no mechanical problem on which a greater amount of intellectual ingenuity has been wasted than that which has for its object the discovery of the perpetual motion. Since this term, however, is not always rightly understood, it will be useful here to explain what the perpetual motion is not, as well as what it is.

The perpetual motion, then, which has been the subject of such anxious and laborious research is not a mere motion, which is continued indefinitely. If it were, the diurnal and annual motion of the earth, and the corresponding motions of the other planets and satellites of the solar system, as well as the rotations of the sun upon its axis, would be all perpetual motions.

To understand the object of this celebrated problem,

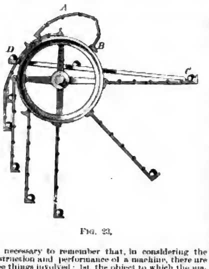

FIG. 23.

it is necessary to remember that, in considering the construction and performance of a machine, there are three things involved: 1st, the object to which the machine gives motion; 2d, the construction of the mechanism; and 3d, the moving power, the effect of which is transmitted by the machine to the object to be moved. In consequence of the inertia of matter, the machine cannot transmit to the object more force than it receives from the moving power; strictly speaking, indeed, it must transmit less force, since more or less of the moving force must be intercepted by friction and atmospheric resistance. If, therefore, it were proposed to invent a machine which would transmit to the object to be moved the whole amount of force imparted by the moving power, such a problem would be at once pronounced impossible of solution, inasmuch as it would involve two impracticable conditions: first, the absence of atmospheric resistance, which would oblige the machine to be worked in a vacuum; and second, the absence of all friction between those parts of the machine which would move in contact with one another.

But suppose that it were proposed to invent a machine which would transmit to the object to be moved a greater amount of force than that imparted by the moving power, the impossibility of the problem would in this case be still more glaring; for, even though the machine were to work in a vacuum, and all friction were removed, it could do no more than convey to the object the force it receives. To suppose that it could convey more force, it would be necessary to admit that the surplus must be produced by the machine itself, and that, consequently, the matter composing it would not be endowed with the quality of inertia. Such a supposition would be equivalent to ascribing to the machine the qualities of an animated being.

But the absurdity would be still greater, if possible, if the problem were to invent a machine which would impart a certain motion to an object without receiving any force whatever from a moving power; yet such is precisely the celebrated problem of the perpetual motion.

In short, a perpetual motion would be, for example, a watch or clock which would go as long as its mechanism would endure, without being wound up; it would be a mill which would grind corn, or work machinery, without the action upon it of water, wind, steam, animal power, or any other moving force external to it.

It is not only true that such a machine never has been invented, but it is demonstrable that so long as

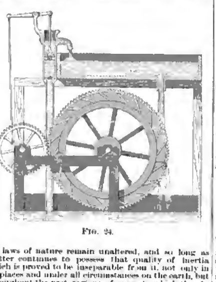

FIG. 24.

the laws of nature remain unaltered, and so long as matter continues to possess that quality of inertia which is proved to be inseparable from it, not only in all places and under all circumstances on the earth, but throughout the vast regions of space to which the observations of astronomers have extended, the invention of such a machine is an impossibility the most absolute.

Fig. 22 is a drawing of a supposed perpetual motion, which the inventor says will not go, though he has worked at it twelve months. He has now given it up in despair, and vows he will waste no more time upon it. The central weights, A, each weigh one-fourth more than the weights, B, at the extremities of the arms. The two sets of weights are connected pairs, each pair being joined by a lever, link and bell crank, C. The action of gravity in the central weights compels the sliding weights at the ends of the arms to assume the positions shown in the engraving.

Had our correspondent, Mr. George C. Phillips, of Alleghany, Cal., applied a little mathematical calculation to the verification of the truth or falsity of the principle of his device, he might easily have proved that it was a perfect balance, and saved himself twelve months of trouble and expense. The leverage of the outside is exactly counteracted by the leverage of the inside weights.

Fig. 23 is a device contrived by Mr. George Linton, of Middlesex, England. The engraving is an end view of a series of vertical wheels, one only being seen. The lever, A, is represented in the act of falling from the periphery of the wheel into a right line. The lever is composed of a series of flat rods, connected by ruler joints, which said ruler joints are provided with a stop, or joggle, to prevent their collapsing at any time more than will bring any one of the rods which compose the levers at a right angle with the rod next to it. This lever is attached to the periphery of the wheel by the hinge joint, B, provided with the shoulder, to prevent its falling into any other than a right line from the center of the circumference of the wheel. The levers are furnished at their outer extremities with a bucket, or receiver, the bottom of which is sufficiently broad to retain the ball, C. The balls remain in the buckets till the buckets come into the position of the lever, D, when they are expected to roll out of the buckets on to the inclined plane, and by their own gravity roll to the other end of the inclined plane, ready to be again taken into the buckets.

Fig. 24 shows a principle so often employed for the production of self-moving machines that it ranks next to that of perpetual eccentric weights in its delusive power upon minds of inventors. The attempt to compel a water wheel to raise the water which drives it is in one form or other perpetually recurring in devices

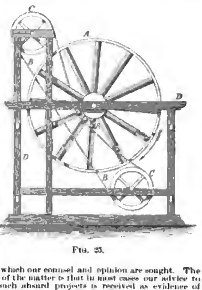

FIG. 25.

upon which our counsel and opinion are sought. The worst of the matter is that in most cases our advice to drop such absurd projects is received as evidence of our want of sagacity and knowledge, and our would-be client becomes the dupe of some not over-conscientious patent agent, who pockets his fees and laughs in his sleeve at the greenness of the applicant.

The device illustrated is one submitted by one of these enthusiastic individuals, who, without understanding the first principles of mechanics, believes he is about to revolutionize the industry of the world by his grand discovery; and as honor, and not pecuniary reward, is his object, he seeks to make public his invention through the wide circulation of this journal. He is quite willing we should adversely criticise the device, because its merits are so great that no amount of skepticism resulting from our blind prejudice can, he thinks, influence candid minds against a principle so obviously sound and sublimely simple. It is unnecessary for us to describe the device, as it explains itself. The inventor has not tried it to see whether it will work. What need when anyone can see on paper that "it must go"?

Fig. 25 represents an attempt at securing the desired object by means of eccentric weights, kept so by means of an endless belt and pulleys, of which the inventor thus writes:

"The annexed drawing shows how I have at length taken this enticing jilt (perpetual motion), though after a long and weary chase

'Through pleasant and delightful fields,
Through barren tracks and lonely wilds;
'Mongst quagmires, mosses, muirs and marshes,
Where dell or spunkie never scarce is!
By chance I happened on her den
And took her where she didna ken.'

"A represents a wheel with twelve hollow spokes, in each of which there is a rolling weight or ball. It is a belt passing over two pulleys, C. There is an opening round the wheel from the nave to the circumference, so as to allow the belt to pass freely and to meet the weights. The weights are met by the belt as the wheel revolves, and are raised from the circumference until they are at last brought close to the nave, where they remain till, by the revolution of the wheel, they are allowed to roll out through the circumference. By this

* Reprinted from the SCIENTIFIC AMERICAN, 1870-71.

arrangement the weights are one side of the wheel, always at the circumference, so that that side is more powerful than the other, which causes the wheel continually to revolve. D is the frame of the machine. The arrow points out the direction in which the wheel turns."—Dixon Vallance, Liberton, Lanarkshire, November 10, 1825.

In 1612 Thomas Tymme, professor of divinity, published a philosophical dialogue, in which he discourses of the perpetual motion invented by Cornelius Van Drebble, a Dutchman, who was engineer to King James in England.

Tymme's work is a small quarto. The author's name on the title papers occurs in the smallest type. It is repeated again in full—"Thomas Tymme"—both to the dedication "To the Right Honorable Sir Edward Coke, Lord Chief Justice," etc., etc., and also The Address to the Readers, which latter concludes:

"And for that rare things move much, I have thought it pertinent to this Treatise, to set before thee a most strange and wittie invention of another Archimedes which concerneth Artificial perpetual motion, imitating nature by a lively patterne of the Instrument It Selfe, as it was presented to the King's Most Royall hands, by Cornelius Drebble, of Alchmar in Holland, and entertained according to the worthinesse of such, a gift my paines herein bestowed and intended for thy profit and pleasure, if it seeme but as iron, yet let it serve for the Forge and Anvil of good conceit, if the discourse seeme rough, shadow it, I pray thee, with the curtaine of smooth excuse," etc.

The work is divided into two parts, the first containing six, the second four chapters.

"Chap. 3 concerneth the nature and qualitie of the earth: and the handling of a question whether the earth hath naturall motion or no.

"Also herein is described an Instrument of Perpetuall Motion, as stated in the list of Contents."

At page 56 commences chapter 3, from which we extract the following:

"Philadelphia—For as much as the Earth and Sea make but one globous body united and combined together, I pray you describe the form thereof to me."

This is explained by Theophrast—the dialogue occupying four pages. At last he says:

" . . . And to make plaine the demonstration unto you, that the Heavens move and not the earth, I will set before you a memorable Modell and Patterne, respecting the motion of the Heavens about the fixed earth, made by Art in the immitation of Nature, by a gentleman of Holland, named Cornelius Drebble, which instrument is perpetually in motion without the means of Steele, Springs, and waights.

"Phil.—I much desire to see this strange Invention. Therefore, I pray thee, good Theophrast, set it here before me, and the use thereof.

"Theo.—It is not in my hands to show, but in the custody of King James, to whom it was presented. But yet behold the description thereof here after fixed.

"Phil.—What use hath the globe marked with the letter A?

"Theo.—It representeth the Earth; and it containeth in the hollow body thereof divers wheels of brasse, carried about with moving, two pointers on each side of the Globe does proportion and shew forth the time of dayes, moneths, and yeeres, like a perpetualle Almanacke.

"Phil.—Both doth it also represent and set forth the motions of the Heavens?

"Theo.—It setteth forth these particulars of Celestiall motion. First the houres of the rising and setting of the Sunne, from day to day continually. Secondly, hereby is to be seene, what signe the Motion is in every 24 houres. Thirdly, in what degree the Sunne is distant from the Moone. Fourthly, how many degrees the Sunne and Moone are distant from us every houre of the day and night. Fifthly, in what signe of the Zodiacke, the sun is every Moneth.

"Phil.—What doeth the circumference represent, which compasseth the Globe about?

"Theo.—That circumference is a ring of Cristall glass, which being hollow, hath in it water, representing the sea, which water riseth and falleth, as doth the flood, and ebbe twice in 24 houres, according to the course of the tides in those parts, there this instrument shall be placed, whereby is to be seene how the Tides keepe their course by day or by night.

"Phil.—What meaneth the little globe above the ringe of the Glasse?

"Theo.—That little Globe as it carrieth the forme of moone cressent, so it turneth about once in a moneth, setting forth the encrease and decrease of the Moone's brightnesse, from the wane to the full, by turning round every moneth in the yeere.

"Phil.—Can you yeeld me any reason to perswade me concerning the possibility of the perpetuity of this motion?

"Theo.—You have heard before that fire is the most active and powerful Element, and the cause of all motion in nature. This was well knowne to Cornelius, by his practise in the untwining of the elements, and therefore to the effecting of this great worke, he extracted a fierie spirit, out of the minerall matter, joining the same with his proper aire, which encluded in the Axletree, being hollow, carrieth the wheeles, making a continuall rotation or revolution, except issue or vent be given to the Axletree, whereby that imprisoned spirit may get forth. I am bold thus to conjecture because I did at sundry times pry into the practise of this gentleman with whom I was very familiar. Moreover, when as the King, our Soveraigne, could hardly believe that this motion should be perpetuall, except the misterie were revealed unto him; this cunning Bezaleel, in secret manner, disclosed to his Majestie the secret, whereupon he applauded the rare invention. The fame thereof caused the Emperor to entreat his most excellent Majestie to license Cornelius Bezaleel to come to his Court, there to effect the like Instruments for him, sending unto Cornelius a rich chaine of gold.

"Phil. It becometh not me to make question concerning the certaintie of that, which so might Potentates out of the finity of their wisdomes have approved, yet me thinketh that time and rust which corrupteth and weareth out all earthly things, may bring an end to this motion in a few yeeres.

"Theo.—To the end of time may not weare these wheeles by their motion you must know that they move in such slow measure that they cannot weare and the losse, for that they are not forced by any poyse of waight. It is reported in the Preface of Euclydes Elements, by John Dee, that he and Hieronimus Cardanus saw and Instrument of perpetuall motion, which was solde for 20 talents of gold, and after presented to Charles Fift Emperour; wherein was one wheele of such invisible motion that in 70 yeeres onely his owne period should be finished. Such slow motion cannot weare the wheeles. And to the end rust may not cause decay, every Engine belonging to this Instrument is double gilded with fine gold, which preserveth from rust and corruption.

"Phil.—This wonderful demonstration of Artificiall motion, immitating the motion celestiall, about the fixed earth doth more prevaill with me to approve your reasons before alleadged, concerning the moving of the Heavens, and the stability of the Earth then can Copernicus assertions which concerne the motion of the Earth. I have heard and read of manie strange motions artificiall as were the inventions of Boetius."

After enumerating these and others Phil. concludes:

"These were ingenious inventions, but none of them are comparable to this perpetuall motion here described, which time by triall in ages to come, will much commend.

"Theo.—These great misteries were attained by spending more oyle than wine; by taking more paines than following pleasure."

(To be continued.)

SHOULD GENERATING PLANT BE MOUNTED ON SPRINGS?*

By JAMES SWINBURNE, M.Inst.C.E.

THIS is really part of a larger question: Should moving machinery be mounted on springs? The question concerns both the health of the moving machinery and of the people who may be moved by it. In central stations and in passenger steamers the shaking caused by machinery is most serious; in flour mills, for example, it is rather a question concerning the gear itself.

If we consider, say, a direct acting pump in space, it is a system that of course cannot move its center of gravity as a whole. If, then, its pistons and plunger move in one direction, the rest must move in another direction, the distance depending on their masses. Any imperfectly balanced machinery must therefore move its bedplate if freely suspended. A perfectly balanced engine is thus an engine whose center of gravity never varies relatively to its bedplate. This definition is really too small, because a moving system, such, for instance, as two cranks at 180 deg. on opposite ends of a shaft, do not change their center of gravity, but give the bedplate a rocking but nontranslational movement. A gas engine with a flywheel, similarly, tends to rotate its bedplate at each impulse round an axis parallel to that of the shaft. A balanced engine is therefore really one which does not move its bedplate if freely suspended. Such an engine is practically never realized.

When an engineer sees an engine bedplate moving, his first instinct is to bolt it down; it then moves a little less, but still moves, and he has a sort of feeling it must shake itself to pieces if allowed to move. Bolting down an engine to a bed of concrete is merely increasing the size of its effective bedplate, but the whole bedplate, including the concrete, must now be moved. It rests on the earth, moves slightly, and communicates vibration to neighbors who are longing to be compensated for disturbance.

Sometimes the concrete bedplate is isolated by mounting it on felt; that means that the larger bedplate is mounted on rather imperfect springs.

A rather striking case is that of church bells. Bells are very much out of balance, and the bedplates are mere cages of timber; so the bedplates would tend to move a good deal. The bell people do not like to see it move, so they wedge it to the steeple, and the result is a cracked steeple. The consequence is that you often hear that such a church has a very fine peal of bells, but they cannot be used, as the steeple will not stand it. Though this may be a relief to people whose ears are in tune, it might be cheaper not to make bells than to make them and hang them so that they cannot be used.

The question is, if the bedplate of an engine wants to move, why should it not have free play? As far as the engine goes, a little thought will show that all its parts are subjected to smaller stresses if the bedplate is free to move. An engine will therefore wear longer if it is allowed to move its bedplate. As to the foundations, if the bedplate is allowed to move, no foundations to speak of are needed; and there is no vibration communicated to the ground.

The writer has tried this arrangement on a small scale. There is a small dynamotor on one of the top floors of Mr. Crookes' house which is very much out of balance, and rendered the house uninhabitable at first. It is now on springs and makes no noise. There is also a dynamotor for electrolytic work in the writer's laboratory. It has no springs, and no one has any inkling of a chance of complaining.

In passenger steamers the throb of the engine is exceedingly unpleasant; in fact, many people would rather go by a slower boat than travel 21 knots and be at the same time shaken 42 more knots by his pedometer. Mounting marine engines on springs seems rather a bold suggestion, and perhaps we ought not to begin there. The moving systems are so heavy in proportion to the fixed (or "attached" is the better word) that the marine engine is a particularly difficult case.

The idea of mounting engines and dynamos on springs was mooted by the writer in Industries in 1892. The editor, in addition to being a sound engineer, is a man of caution, so the communication came out as an anonymous letter. Mr. W. W. Beaumont has, however, done a great deal of real work on the subject, especially in connection with flour mills. He has introduced his "vibromotor" principle. This principle is simple, "If gear wants to wobble, let it wobble." The idea seems sound. The discussion will perhaps throw new light on it.

* Paper read at the Institution of Civil Engineers. Engineering Conference. Section VII. Applications of Electricity.

The administration of oxygen is of great benefit in the case of carbon monoxide poisoning.—Stahl und Eisen.

SELECTED FORMULÆ.

Electro-plating Aluminum with Copper.—According to a continental contemporary, it is possible to obtain adhesive coats of copper on aluminum by the following method: First clean the aluminum in a warm solution of an alkaline carbonate, thus making its surface rough and porous; it is next washed thoroughly in running water, and dipped into a hot solution of hydrochloric acid of about 5 per cent strength, again washed in clean water, and then placed in a somewhat concentrated acid solution of copper sulphate, until a uniform metallic deposit is formed; it is then again thoroughly washed and returned to the copper sulphate bath, when an electric current is passed until a coating of copper of the required thickness is obtained.

Photographic Intensification.—A method of optical intensification of a weak negative, due to Lord Rayleigh, is too valuable to be overlooked. It is based upon a well known principle. A piece of colored glass looks twice as intensely colored when placed upon a sheet of white paper. A feeble transparency is similarly intensified. In both cases the light rays have to traverse the absorbing layer twice over. For the white paper a silver-on-glass mirror may be advantageously substituted. The film of the negative is placed in contact with the silver, and illuminated by a candle or other small source of light. It is then photographed in the usual manner. To get rid of surface reflection a wedge shaped plate of glass is laid over the negative.—Rayleigh, Phil. Mag., Sept., 1897.

Model Face Powder.—The Pharmaceutische Rundschau says that a good face powder must contain snow-white steatite, light calcium carbonate, zinc white and wheat or rice starch. Flesh color for blonds is produced by carmine and the tint for brunettes by burnt umber or sienna. Orris is best for scent. The following ideal cosmetic powder is constructed from these ingredients:

Zinc white	500	parts.
English precipitated calcium carbonate	8000	"
Steatite, best white	500	"
Wheat or rice starch	1000	"
Triple extract white rose	30	"
Triple extract jasmine	30	"
Triple extract orange flower	30	"
Extract cassia	30	"
Tincture musk	8	"

Mix thoroughly by repeated siftings. Orris root in powder may be substituted for the perfumes.—Pharmaceutical Era.

Pumice Stone for Filtering.—English pharmacists are generally familiar with the valuable properties of pumice stone as a filtering medium, which Busch (Pharm. Centralh., xxxviii, 424) has lately recommended as a novelty for filtering liquids which contain minutely distributed precipitates (such as barium sulphate, lead sulphate, calcium oxalate), likely to pass through the filter. The very finest pumice stone powder must be used, and it must have been freed from all acid-soluble impurities. Two to three grains of the powder are put on the point of the filter, and a clear filtrate is said to be obtained after the first few drops.

Detection of Glycerine in Sirupy Liquids.—Denigès recommends heating a small quantity of the liquid with three or four times its weight of powdered bisulphate of potassium. Any acrolein vapors which may have formed are detected by Nessler's reagent, or they are passed into a hot mixture of 2 c.c. of a 1 to 2 solution of silver nitrate, 2 c.c. of solution of ammonia and 2 c.c. of solution of soda. The reduction of the silver solution indicates the presence of glycerine.—Pharm. Centralh., xxxviii, 427.

New Dental Filling Material.—The following mixture under the name of "aluminized gutta percha" is recommended by Bliss as a filling:

White gutta percha	8
Aluminum filings	5
Oxide of zinc	1
Whiting	½

The filling is said to be easily manipulated, free from bulging and to hold its position in the cavity when firmly packed.—Journ. Brit. Dent. Ass., xviii, 401, after Pac. Stomat. Gaz.

Coloring Silver.—A rich gold tint may be imparted to silver articles by plunging them into dilute sulphuric acid, saturated with iron rust.—La Science en Famille.

Blacking Copper.—To give a copper article a black covering, clean it with emery paper, heat gently in a Bunsen or a spirit flame, immerse for 10 seconds in a solution of copper filings in dilute nitric acid, and heat again.—Revue Scientifique.

Waterproof Floors.—Flooring may be made impermeable by painting it with a solution of paraffin wax in kerosene. The coat lasts for two years.—Uhland's Wochenschrift.

Soldering Cast Iron.—To solder cast iron, clean the place to be soldered well, then brush it with a brass wire brush until the iron becomes yellow. It will be found that the solder can now be applied without any trouble.—La Science en Famille.

Developing Powders.—A developer in powder form, suitable for taking on tours, is prepared as follows:

A

Metol	7	parts.
Hydroquinone	18¼	"
Powdered eikonogen	10½	"
Powdered boric acid	4½	"

Mix this well and keep in a well stoppered yellow bottle.

B

Sulphite of soda	45	parts.
Borax	10½	"
Sugar of milk	10½	"

This may be kept in a white bottle. For use take:

Water	100	parts.
Powder A	2	"
Powder B	4	"

For bromide paper use double the amount of water.—La Vie Scientifique.

ENGINEERING NOTES.

An overhead cable tramway, from Dyea to the Klondike mines, is proposed by L. R. Radcliff, of St. Louis. The St. Louis Republic says that he is now preparing to ship his cables and machinery to Seattle and thence to the far North, with the intention of building his tramway in the next spring and have it in working order over the pass for the following winter. Meanwhile he also proposes warehouse stations along the proposed line, to be worked by burros for the transport of miners' supplies.

A railway to India, from Alexandria to Agra and Bombay, is proposed by C. E. D. Black, in a paper read before the English Society of Arts. The line would be 2,400 miles long, from Port Said to Kurrachee, and would cross upper Arabia to Basra, at the head of the Persian Gulf; and skirt the north shore of the gulf and the Arabian Sea to Kurrachee, on the border of India. Mr. Black advocates the route for political purposes mainly, though he thinks the revenue would be sufficient to pay a fair interest on its estimated cost of $75,000,000.

Success appears to have attended the experiment made last December on the New Haven Railroad, and duly reported at the time, in the sheathing of a passenger car with copper. In this case the usual sheathing was removed from a first-class car, the frame was redressed and blocked and the metal sheathing was prepared in the company's shop, the process being slow, as the work was out of the usual line. It was thought that the copper might add considerably to the weight of the car, but since the completion of the work it has been found that the thinner car sheathing is not desirable, for the reason that the lips of the grooves in the edge are inclined to curl, there not being sufficient lumber in the upper lip to make it firm. All the posts and corners, in fact, every exterior part of the passenger car made of wood, were covered with copper. The car has been run since January without interruption, and no appreciable evidence of expansion has been noted during exposure to heat or cold, and the stiffness of the material prevents bad appearance on the board. Some eight hundred to nine hundred pounds of metal are required.

The greatest steam hammer of Germany is still the one called "Fritz," at the Krupp Works in Essen, but, although great care had been taken in providing a very strong foundation, it has settled almost 10 inches. The construction of the foundation was started in a hole 40 feet deep on a grill made of piling. Then there comes a deep layer of sawdust, upon which very large and heavy cast steel blocks solidly fastened to each other are resting. Next follow three alternate layers of heavy wooden planking and more steel blocks. On top there is a layer of cork 40 inches thick, carrying the anvil block, which weighs upward of 30 tons. This foundation has to carry a total weight of about 2,300 tons, and, in consequence of its settling, the hammer is but seldom used now, having been replaced by a hydraulic press able to exert a pressure of 12,500 tons. This hydraulic press is the largest at the present time in Continental Europe, England being the only country having one of the same size, at the foundry of Beadmore, at Parkhead. In this connection it may be interesting to note that the Bethlehem Iron Works have now a hydraulic press furnishing an equivalent of power of 14,000 tons pressure.

That galvanized sheets which are made of steel with the oxide formed in rolling removed, and then coated with spelter, are not more generally used in boiler or tank works is because the advantages thereof are not sufficiently understood, says the American Boilermaker. The extreme cheapness of steel plate and improvement in manipulating same has been followed by the general substitution of steel plate stacks and chimneys for brick. It is, however, well for boilermakers to remember that the action of moisture, especially when impregnated with sulphur arising from soft coal, has a destructive influence on steel plates, rusting rapidly, particularly in the lighter gages. This may be delayed by frequent painting or varnishing. The coating of spelter of steel sheets is impervious to moisture, and therefore the life of the metal is preserved indefinitely, especially where it may be painted with the ordinary commercial stack or boiler paints. We would remind boilermakers that, unless they call the attention of their customers to this fact, they will find a large and profitable part of their business leaving them on account of the short life of the ordinary steel stack as now made, because the first cost of the brick chimneys will be of less importance than the inconvenience and cost of having to replace a steel stack or chimney.

Various plans have been suggested at different times for the utilization of the energy developed by the rise and fall of the tides, but the intermittent character of the power has usually prevented any satisfactory solution of the problem. There is, however, one instance in which tide power has been quite successfully applied in a very simple manner. Along the river front at Liverpool there is a tendency for the accumulation of silt against the dock walls, requiring occasional dredging for its removal. Instead of using scoop dredges, this mud is removed at different periods by the use of tide power in the following manner: Along the base of the dock walls is laid a pipe, perforated with holes, directed outward, this pipe being connected with the interior of the dock system, and suitable valves being provided to permit or to check the flow of water. When the tide is very low, and consequently the head of water measured from the surface in the docks is at its greatest, a sudden opening of the connection permits a rapid flushing action by the water escaping through holes in the pipe at the base of the walls, scouring out the mud and driving it out into the river to be carried away. As the tides at Liverpool average about 25 ft. or more, it is evident that this simple form of dredging apparatus may be very effective, and as the time chosen for using it may be selected when the supply of water is greatest, it does not interfere with the regular use of the docks. Ultimately, no doubt the introduction of practical and economical forms of power storage will render the equalization of tide power commercially practicable, but at the present time this example serves to demonstrate the fact that solar and lunar attraction, as expressed by the tides, have been harnessed in a small way at least.

ELECTRICAL NOTES.

A telephone connection between Frankfort-on-the-Main (Germany) and the chief towns of Switzerland is planned.—Electrotechnische Rundschau.

Herr Otto Reincke remarks that wines and beer are cleared much more quickly of any suspended matter if under direct strong light. He has tried the effect of the light from an electric lamp, and has found that a very quick clarification could be effected by the action of its rays on the beverage.—Wochenschrift für Brauerei.

The great station of the Niagara Falls Power Company is being extended 286 ft., making its total length 436 ft., which will accommodate ten of the 5,000 horse power units, three of which are already in place and seven more contracted for, the Westinghouse Company supplying the generators and the I. P. Morris Company the turbines, as before.

In Baar, Switzerland, there is a 10,000 spindle cotton mill run by electric power from the Rhone, which is only 550 feet away, says the Electrical Review. There are three motors kept in a separate room to protect them from the dust, and of these one drives the openers, cards, combing machines, drawing and flier frames, and supplies 200 lamps; another drives the mules, and the third the ventilating fan and workshop.

It is said that interesting experiments are being carried on by the Carnegie Steel Company at its Homestead Works in heating steel billets by electricity, says the English Electrical Review. Economy in fuel and a saving in time required to heat the billets are claimed. It is also asserted that the billets are heated from the center to the outer surface, insuring equal heat throughout the mass. The steel thus treated is reported to be of better quality, from the fact that the exact temperature may be obtained without overheating.

At Genoa (Italy) a peculiar accident recently occurred. A troop of soldiers were on their way to their drill, and were led by Lieutenant Tallio. The latter was crossing the tracks of the electric cars, when his horse stumbled, and knocked its head against one of the iron posts which carry the wires. A long spark shot out of the post and killed the horse instantly. The lieutenant was unhurt. The company explained the fact, saying that in a recent thunderstorm the post had been struck by lightning, and the insulation destroyed, so that the horse short-circuited the rails and the wires.—Electrotechnische Rundschau.

The electric current is supplied by some companies at a tariff based on the use of lamps of a definite candlepower. In many cases, either intentionally or by error, lamps of too high a candlepower are used. Thus the company is defrauded of its due. A device has now been introduced which makes it impossible to use lamps of a higher candlepower than provided by the tariff. Within the threaded socket of the lamp are placed a series of rings, varying in number according to the candlepower of the lamp, such of low candlepower having more rings than those of higher candlepower. Consequently, a lamp inserted in a socket intended for one of higher candlepower produces no contact, and therefore gives no light.—Stahl und Eisen.

"**The only** tramway company in Siam," says Mr. J. Barrett, in the Street Railway Journal, "is the Bangkok Tramways Company, which has been organized several years and is doing a very successful business. It began with horse cars, but now has as good an electrical equipment as most lines in America. When the system was changed from horses to electricity, the contract for dynamos, rolling stock and work of alteration was given to an American firm, who sent out a competent engineer to superintend it. From the very first day that the line was operated by electricity it has paid handsome dividends, never less than 8 or 10 per cent. and running up in one or two years to 15 or 18 per cent. per annum. The Siamese government has been favorably disposed to the company from its inception, and the King is a large stockholder. The Siamese people seem to have no prejudice whatever against this or other modern systems of rapid transit, and crowd the cars at every trip. The line has been so prosperous that it is running all the cars possible. It has a single track, with switches about every quarter of a mile, the streets being too narrow for a double track. The road runs right away from the lower end of the city in the heart of the shipping interests to the royal palace, a distance of fully six miles, through the principal thoroughfare. . . ."

The principal feature of the Cowper-Coles gold recovery process is an aluminum cathode which overcomes one of the chief difficulties appertaining to the economical recovery of gold from weak cyanide solutions by electrolysis, says The Engineer. In the Siemens-Halske process lead foil or lead strips are used, the cutting up of which is a tedious matter. If several sheets are cut superimposed, the strips cling together, and have to be carefully spread out one by one, so that the surface may be exposed to the solution. A clean-up is made every seven to eight weeks, when the wood frames carrying the lead strips are withdrawn, the lead strips removed and new substituted, the auriferous lead being ultimately melted down, and conveyed to a central works to be cupeled. This method is both crude and expensive, the labor of fitting the strips into the frames is considerable, and the consumption of lead is a large item, having been computed by Mr. Von Gernet at the Worcester Mine at 1·10 of a penny per ton of ore treated. The Cowper-Coles process overcomes these difficulties, aluminum plates being substituted for the lead foil, advantage being taken of the fact that a loose oxide is formed on the surface of the aluminum which enables the deposited gold to be readily stripped or wiped from the cathodes as pure gold. Gold by this process has been successfully extracted from cyanide solutions containing only 0·01 per cent. of cyanide of potassium, 2¼ dwt. of gold to the ton of solution. The substitution of aluminum for lead foil, or strip, enables the gold to be obtained as pure gold, and also daily returns to be made of the amount of gold recovered; it also has the additional advantage of reducing the cost of labor and economizing the amount of cyanide of potassium used, as the solution is not contaminated by any base metals such as zinc, as in the other processes.

MISCELLANEOUS NOTES.

The population of Algiers has risen from 4,164,158 in 1891 to 4,394,129 in 1896. These numbers include the French troops: 345,337 are French, 3,755,917 are Mohammedans of French nationality, the remainder consists of Spaniards, native Jews, Italians, Tunisians, Moors, Maltese, Germans, and others.—La Science en Famille.

Herr Russner, in Mittheilungen aus der Praxis des Dampfkessel- und Dampfmaschinen-Betriebes, 1896, states by using a covering of zinc plate on steam pipes, leaving a layer of air between the pipe and the covering, the condensation can be much reduced. Experiments with this contrivance gave results which compare by no means unfavorably with those of the ordinary non-conducting coverings, while the new arrangements have certain advantages which the author points out.

There are several breweries in Japan which are in keen competition both as regards the inland supply and the export. Their prosperity is best shown by the rise in the fortunes of the greatest among them, the "Nihon Bakushu-Kwaisha." Five or six years ago this company was very near bankruptcy, but in 1895 it sold three times as much beer as in 1892. Its shares advanced from 40 yen to 80 yen and from 12½ yen to 34 yen. The exports of German beer to India and other parts of Asia have gone down in the proportion of 9·5 : 8.

Herr Salzenberg has devised a system of incandescent gas burners in which the gas is used at a high pressure. For the source of pressure he uses the water pipes. With his burner a candle power of 850 to 1,000 is obtained by the combustion of 230 to 300 liters of gas and about a cubic yard of water per hour. From one mantle two and one-half times as much light can be obtained as from an arc lamp, the expenses being much lower—the arc lamps burning in Germany costing about fifteen cents per hour, the incandescent gas three cents.—Uhland's Wochenschrift.

A great many toys are now made in this country, including many mechanical devices. Many toys are still imported. Such things as woolly sheep and dogs, now as highly prized by children as ever, come from Germany, as do the skin-covered horses. They could be made here, but they can be produced cheaper abroad. As a rule, whatever can be made by machinery is made here, while toys made by hand are mostly imported. The minute a thing is brought within the reach of machinery, American manufacturers can pay their higher prices for labor and still beat the world. With the low prices of labor in foreign countries, hand-made productions can be made cheaper in them. As a result of this there are toys of some kinds which in their completed state are partly American and partly foreign. Among these are toy vehicles with horses attached. The vehicles and everything in and about them may be the product of American machinery, while the horse standing between the shafts may be from Germany.

The separation of tin and wolfram ore has been successfully accomplished by means of the Wetherill magnetic concentrator, says the Iron and Coal Trades Review. The ore upon which the experiments were made was from Spain, and consisted of cassiterite contaminated by wolframite. Wolfram in tin ore is a very objectionable element, and ordinarily its elimination involves a tedious and unsatisfactory process. Simple mechanical separation is impossible, since the specific gravity of wolframite is very similar to that of cassiterite. With the Wetherill machine, however, a nearly perfect separation was effected. The wolframite, besides being removed from the tin ore, was converted into a clean, marketable product for ferro-tungsten manufacture. The ores of which wolfram was the bane are no longer very important sources of tin supply, and the Bohemian and Saxon mines which furnish a good deal of wolframite have comparatively little cassiterite associated with them, so that the scope of the Wetherill machine is limited to the inferior Spanish ores, which were the subject of the experiments.

According to Dingler's Polytechnisches Journal, July 9, the question of carborundum versus emery is at present occupying much attention in Europe, says the Engineering and Mining Journal. In emery the abrasive material is crystallized aluminum oxide; in carborundum it is carbide of silicon. Although carborundum is much harder, its crystalline structure is less favorable for grinding than is emery. The crystals of carborundum are long and narrow, with few cutting edges and smooth faces, while emery crystals are nearly cubical and have rough surfaces. Perhaps the greater hardness of carborundum is offset by the better cutting properties of the emery. This is also indicated by the difficulty in keeping carborundum wheels from glazing when too much slag is used in making them. The author of the paper quoted concludes that emery has the advantage over carborundum for grinding or polishing purposes in all cases except where the finest grades are used. For the latter, carborundum seems to be the better.

The Chemiker Zeitung in a recent issue says that in aluminum castings a distinction must be drawn between castings which are practically finished on leaving the mould and castings which are subsequently subjected to a forging or rolling process. The difficulty of producing sound aluminum castings lies in the great contraction of the metal on cooling. This difficulty can be overcome by adding phosphorus to the molten metal, in the proportion of about one gramme to one kilogramme. Thoroughly sound castings are obtained in this manner, but they are rather brittle, and therefore unfit for rolling purposes. Castings suitable for the last named process are obtained by pouring some rape oil upon the surface of the metal, which is fused in iron crucibles. When all the oil is burnt off, the metal is run in the hot iron moulds, and as soon as the contraction begins more metal is added. The ingots obtained in this way are excellent for rolling, forging or wire drawing purposes. Aluminum fused in graphite crucibles always has a tendency to crack in the rolling or forging, the more so the oftener it has undergone the process of melting in this kind of crucible. This appears to be due to the fact that aluminum takes up silicon from the crucible.

EXPERIENCES IN THE ARCTIC SEAS.

FREDERICK G. JACKSON, the leader of the Jackson-Harmsworth polar expedition, has given, in a recent issue of the London Graphic, an interesting account of his experiences in Arctic exploration and describes as follows how he happened to make his first voyage to the polar regions:

It was in the winter of 1887, while in the Southern States of America, that I received a cablegram from a friend, who, being aware of my desires, told me that if I could be ready to go, and in Peterhead within three weeks, a passage had been offered to me in a whaler leaving that port in the first week of March. In three days I had settled up my affairs and left on the first stage of my journey toward the north. The voyage I then embarked upon in the good ship Eric, under the able command of Captain Alec Gray, in some respects changed my preconceived notions of the world within the Arctic circle and enlarged my ideas, but without reducing my enthusiasm in the smallest degree.

In 1892 I drew up and made public the plans upon which my recent expedition was based, and with the object of testing my equipment and obtaining some practical experience of sledging and camp life during an Arctic winter, in the summer of 1893 I embarked upon one of the vessels of the Yenesei expedition and was landed with my stores and sledges at the Yugor Straits. Here I was able, in the company of two Samoyads, to map in and explore the island of Waigatz, which is of special interest from being the holy island of these remarkable northern people. To certain sacred spots these Samoyads, from the whole of Northern Siberia and Russia, make pilgrimages, traveling frequently many thousands of miles with this object, and taking sometimes months on the journey. Returning south, I then passed through and mapped the Bolshaia Zemelskija Tundra country, having engaged Samoyads and reindeer for the purpose, and was able to put to severe tests the various parts of my equipment which I intended to use on my Franz Josef Land expedition.

On this journey, after reaching comparative civilization, I fell in with and experienced the great value of the hardy northern Russian horses that I then determined to make use of on that expedition, and which have since fully justified my most sanguine expectations and have done us such good service. On reaching the vice-consulate at Archangel I there found Her Majesty's representative, Mr. Cooke, who gave me a most hearty reception and handed me a cablegram requesting me to return to England with all speed, as the money necessary for my expedition to Franz Josef Land had been found by Mr. Harmsworth, who had even requested Mr. Cooke to dispatch a small expedition in the direction of Khabarova to look for me. This, I felt, was a truly satisfactory result of my journey.

I wished, however, instead of returning via Petersburg, the shortest route, to go round the White Sea and through Lapland, with the object of making further inquiries, of gaining more experience of reindeer, and of studying the clothing and equipment of the Lapps. This I satisfactorily accomplished, and the results, I felt, quite justified the time expended upon this second portion of my long sledge journey.

The next five months were occupied in a great scramble to get everything ready for the expedition to Franz Josef Land. Hurry and bustle was the order of the day, but with very few things in an incomplete condition we sailed in the steam yacht Windward for Franz Josef Land on July 11, 1894. At Archangel we called for a log house we had made and erected with numbered joints to facilitate our again building it in Franz Josef Land. Here we also took on board our four ponies and the bulk of our furs. Our reception by the governor and officials was warm and hospitable in the extreme, and we left the last of civilization behind us carrying pleasant remembrances with us. The next point we made for was Khabarova, where the previous year I had spent some time, and here we took on board thirty dogs brought from the neighborhood of the Ob River for our expedition, and after obtaining a supply of reindeer meat, we steamed north for Franz Josef Land, and our real difficulties began. How we at last got through the icy barrier on September 7, erected our living and store houses and landed our goods upon Cape Flora, and the ship became frozen in for the winter, has already been told.

The following spring, as soon as daylight returned, we began pushing forward toward the north our food depots, in accordance with my plans. In this we were aided enormously by the small horses which we had brought forward with us from Archangel for the purpose, and by the beginning of May we reached latitude 81 deg. 20 min. N., established four food depots at suitable distances apart, and had conveyed north two boats for future use, in addition to making many important geographical discoveries and collections of all kinds. Open water then absolutely stopped our advance, and we were obliged to return to Cape Flora with all speed to avoid losing our ponies owing to the early break up of the ice.

Just prior to our leaving on this journey, a very heavy gale of wind broke up the ice around the ship, and placed her in some peril for a time. A boat lying alongside was swept away, and various other damage was done. As this now left the ship short of boats all hands were set to work to dig two, which I had reserved for the use of the land party, out of the deep snow drifts in which they were buried, and one was taken on board the ship. Directly after the Windward left us in July, we departed on a boat journey along the southwestern coast, and succeeded in adding to Mr. Leigh Smith's discoveries in that direction.

The following winter was passed as comfortably and busily as the previous one and with an equal freedom from illness, and early in the next spring we again started with our sledges north. It was on this journey that my conviction that Franz Josef Land, so far from being a large continental mass as was generally supposed, was in reality but an archipelago of comparatively small islands was confirmed. Open water again met us in the attempt to pass our highest northern latitude of the previous year, but, fortunately, we were able to turn our hands to other geographical work by confirming and adding to that done by us then. The following summer we were fully occupied with scientific work of all kinds, and in the middle of June we met with Nansen and Johansen on their way to the south, having made their wonderful and plucky sledge journey from the farthest north. Never in my life did I experience such keen pleasure as when I was able to welcome these two wanderers to Elmwood and could bid them cast aside their sledges, "kayaks" and "ski," and take their well earned rest. The following winter we were still busier, if possible, than the two that had gone before. New tents, new traces, another canoe, and a thousand and one things had to be attended to. Our absolutely good health still continued, thanks to our doctor's good care of us, and to the ready manner in which the necessary health regulations were complied with by one and all.

On hearing from Dr. Nansen of the non-existence of land to the north, coupled with my own experiences, I decided on completing the map of Franz Josef Land before trying to reach north over the moving pack, and with this object Mr. Armitage and I proceeded up the western shores of the British Channel, of which I completed the mapping, and after a rather tiresome journey of two months, on which, owing to the severe weather, we lost nearly all our draught animals, we succeeded in completing the whole of the western and northwestern shores of Franz Josef Land, and in settling, in my opinion, the for so long vexed question of Gillis Land.

Evia House, on Bell Island, was the scene of a very pleasant little meeting as we neared home. The doctor, having got anxious, owing to our prolonged absence, accompanied by Messrs. Bruce and Wilton, started with a sledge load of provisions to look for us toward the west, but they had only gone ten miles when, on coming up to the hut on Bell Island, they found us encamped inside it.

We remained for ten days at Cape Flora to refit, and Mr. Armitage and I again left with a team of eight rather weak dogs, as I had now hardly any serviceable animals to go east. After doing very well indeed at the outset, when in the neighborhood of Brady Island our sledge broke through the very thin ice, and as we lost all our provisions except a little food put out for lunch, and the ice proving weak in every direction, there was nothing for it but to return. Our chief festivals at Elmwood were Christmas Day, New Year's Day, and birthdays, more especially that of the Queen, when the large jack was run to the head of the flagstaff, and we drank Her Majesty's health in the wine which we kept for such occasions.

FEEDING AN INFANT POLAR BEAR—JACKSON-HARMSWORTH POLAR EXPEDITION.

The post office is laying an underground telegraph cable from London to Birmingham, one of the main reasons of their adopting a long underground trunk line being the difficulty in finding overhead routes. Any additions to the present telephone trunk lines will of course be made above ground, so that it has been deemed advisable to make use of cable for the supplementary telegraph lines which are now required. The cable contains seventy-six conductors laid up in nineteen fours, each conductor weighing 150 lb. per mile. The sets of four conductors are separated by a cross shaped paper core, being held in place by a single lapping of paper, and the nineteen strand is again surrounded by a lapping of broad paper strip. Both these papers are laid on "half-lap," so that each lapping is equivalent to two thicknesses of paper. The whole is contained in a thick lead covering. Work has been begun at Watford, and about nine miles of cable have been laid on each side of the town. The cables are, says the Electrician, drawn into 3 in. cast iron pipes, 30 miles of piping having already been put down. It is intended to use the dry air system to keep up the ventilation of the line.

THE "HEAVY WEIGHTS" COMPETITION OF THE AUTOMOBILE CLUB.

DESPITE the pessimistic predictions of some, the competition of "heavy weight" vehicles (for so they have been styled), which has just taken place (after beginning on the 1st of August and continuing six days), has proved a genuine success for French industry. The minister of war appointed a committee to follow its operations, and several illustrious foreigners came to Paris to be witnesses of it.

This international competition was open to all mechanical vehicles, arranged with a view to the following service:

(1) The carriage of passengers, the vehicles accommodating at least 10 persons and 600 pounds of baggage; and (2) the carriage of freight, and the simultaneous carriage of passengers and freight, with a minimum weight of one ton.

Three itineraries had been selected, having gradients reaching 2 inches to the foot. The carriages started from and returned to Place d'Armes, at Versailles.

The three itineraries were as follows:

A.—St. Cyr, Villepreaux, Noisy-le-roi, Roquencourt, Garches, Saint Cloud, Point-du-Jour, Sèvres, Viroflay and Versailles—say 24·3 miles, 6¼ of which were paved roads, with two refreshment stations.

B.—Ville d'Avray, Montretout, Suresnes, Porte-Maillot, Rueil, Saint Germain, Marly-le-Roy, Roquencourt and Versailles—say 27·5 miles, 3¾ of which were paved roads, with two refreshment stations.

C.—Vaumurier, Dampierre, Cernay-la-Ville, Gif, Palaiseau, Jouy-en-Josas and Versailles—say 39½ miles, of which 6¼ were paved roads, with four refreshment stations.

Each competing vehicle had to pass over each route twice at a speed that was fixed in advance, so that the obstructing of the roads should be reduced to a minimum. The entire journey to be made was thus 183½ miles, 33 of which were over paved roads. One or more judges upon each carriage noted all the important data, incidents or accidents, etc.

We have no intention of giving the details of the competition in this place (for the report that the Automobile Club is preparing will alone be able to teach us as to the official figures taken), but shall be content to calculate the daily total mean speed of each vehicle. The results, of course, are merely approximate, but they nevertheless give indications that are sufficiently practical. This said, we shall pass very rapidly in review the principal types of carriages that competed, in classifying them in three categories: (1) The omnibuses of Messrs. De Dion-Bouton, Panhard, Scotte and Weidknecht; (2) the trains and pleasure cars of Messrs. De Dion-Bouton, Le Blant, and the Maison Parisienne and Scotte; (3) the freight traction engines of Messrs. Dietrich & Scotte.

The De Dion-Bouton Omnibus (Fig. 4).—This carries 16 passengers and their baggage, say 1,050 pounds, and its motor is of 25 horse power. In this vehicle, the builders have employed those parts that have already been put to the test in their steam brakes, etc. (boiler, engine, direct transmission to the wheels, etc.) The engine is placed under the carriage properly so called, and actuates the hind wheels. In front, above the steering train, is placed the boiler, with the conductor and the fireman. The speed upon a level is capable of reaching 10 miles an hour. In reality, the mean speeds (all stoppages included) were: In itinerary A, 7 and 6 miles an hour; in itinerary B, 5½ and 8 miles an hour; and in itinerary C, 8¼ and 5½ miles an hour.

The Panhard Omnibus (Fig. 6).—This carries 10 passengers and 180 pounds of baggage. It is provided with two coupled Daimler-Phenix vertical gasoline motors of 6 horse power, so that in reality it is a 4 cylinder, 12 horse power motor, which is placed under the front seat, and actuates the hind wheels. The transmission is effected through gearings and chains with four differential speeds.

The weight, in running order, is 7,920 pounds. The speed on a level reaches 10 miles an hour. In reality, the mean speeds (all stoppages included) were: Upon itinerary A, 6 and 5 miles an hour; upon itinerary B, 4¼ and 5 miles an hour; and upon itinerary C, 5½ and 4½ miles an hour.

The Scotte Omnibus (Fig. 1).—This carries 12 passengers and their baggage. The motor, which is of 16 horse power, is placed in front, above the steering train. The transmission is by gearings and chains, with two different speeds. The driving wheels are in the rear. The weight, in running order, is four tons. The speed on a level is 9 miles an hour. The mean speeds (all stoppages included) were: Upon itinerary A, 4¼ and 4¼ miles an hour; upon itinerary B, 6 and 4¾ miles an hour; and upon itinerary C, 4¼ and 4¾ miles an hour.

The Weidknecht Omnibus.—This vehicle is of the General Omnibus Company's type of 30 seats. The steam motor, of 34 horse power, acts through chains upon the large front wheels, the steering wheels being behind. The weight in running order is 6 tons. This vehicle was obliged to stop at the end of the third day, in consequence of an accident to the frame. Its mean speed was 3, 3¼ and 3¾ miles an hour upon the three itineraries.

The De Dion-Bouton Traction Engine (Fig. 5).—This hauls a long pleasure car, and has the same mechanical arrangements as the omnibus. It has a seating capacity for 32 passengers without baggage. The mean speeds (all stoppages included) were: Upon itinerary A, 5¼ miles an hour; upon itinerary B, 5 and 5 miles an hour; and upon itinerary C, 4½ and 3½ miles an hour.

Let us say, apropos of this latter figure, that, in consequence of an accident to a connecting rod, the vehicle had to make the second half of its trip with a single engine.

The Le Blant Brake.—This is a carriage that is now old, since it was constructed as far back as 1892, and took a prize in 1894, at the Paris-Rouen competition.

It has accommodations for 12 passengers and 1,100 pounds of baggage. The steam motor is of 12 horse power. The vehicle was put out of service on the very first day, in consequence of a fire occasioned by the smoke stack.

The Maison Parisienne Pleasure Car.—This has accommodations for 12 passengers. It is provided with a 9 horse power ho[illegible]tal gasoline motor of the Benz type. The trans[illegible]on is by belts. Its weight, in running order, is [illegible] pounds. It was run with but half a load, which will throw it out of the competition. Under these conditions it made the average speeds of 5, 6½ and even 8 miles an hour.

The Scotte Train (Fig. 2).—This consists of a motive vehicle, with a seating capacity for 14 persons, hauling a carriage with accommodations for 18 persons and 2,100 pounds of baggage. It is provided with a 16 horse power steam motor having the same mechanical arrangements as those of the omnibus. The mean speed on a level is from 7 to 8¾ miles an hour. The actual speeds obtained were: Upon itinerary A, 4¼ and 4¼ miles an hour; upon itinerary B, 5½ and 4¾ miles an hour; and upon itinerary C, 4¼ and 4½ miles an hour. The running was very regular and sure. Besides, let

FIG. 1.—GENERAL VIEW OF THE SCOTTE OMNIBUS.

FIG. 3.—SCOTTE FREIGHT TRAIN.

FIG. 4.—DE DION-BOUTON OMNIBUS.

FIG. 5.—DE DION-BOUTON TRACTION ENGINE AND PLEASURE CAR.

us recall the fact that an analogous train has been running for a few months past for the public service between Courbevoie and Colombes.

Dietrich's Freight Truck.—This is provided with a 7 horse power gasoline motor, and carries a load of 2,640 pounds. The average speeds (all stoppages included) varied from 4 to 5¾ miles an hour.

The Scotte Freight Train (Fig. 3).—This consists of a traction engine that carries 2¼ tons and of a 9 ton flat car, say 12 tons in all, in running order. The mechanical arrangements are analogous to those of the omnibus and passenger train. The speed on a level is from 4¾ to 6 miles an hour. The mean speeds obtained (stoppages included) varied from 3 to 3¾ miles an hour.

We shall draw no conclusions from the figures that we have just given, having desired merely to present the principal types of the vehicles that competed. After the official report of the Automobile Club of France has been made public we shall be able to appreciate the relative value of the different systems. Let us say merely that the Versailles competition showed that several carriages were capable of a normal and assured operation, and that among these must be mentioned the systems of Scotte, De Dion-Bouton and Panhard and Dietrich.—La Nature.

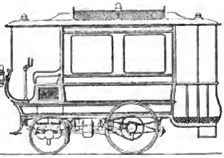

FIG. 6.—PANHARD OMNIBUS.

[Continued from SUPPLEMENT, No. 1135, page 18140.]

THE SPREAD OF LAND SPECIES BY THE AGENCY OF MAN; WITH ESPECIAL REFERENCE TO INSECTS.*

By LELAND O. HOWARD, Ph.D.

THERE remains one more source of accidental introductions, and it is one which has been reasonably prolific as regards insects on several occasions. I refer to international expositions, which are now becoming of almost annual occurrence. At the Centennial Exposition at Philadelphia, in 1876, the insects occurring in the exhibits, especially of foreign grains, received some study by Dr. Riley, who published a short note in the Proceedings of the St. Louis Academy of Science for October 2, 1876. A special committee of the Philadelphia Academy, consisting of Drs. Horn, Leidy and Le Conte, also prepared and published a report at this time, but none but well known and cosmopolitan forms were found. I am not familiar with the results of any studies of a similar nature made at the Paris Exposition Universelle of 1889, but have seen the title of a paper by M. Decaux which reads "Études sur les insectes nuisibles recueillis à l'Exposition Universelle," Paris, 1890, which, however, I have not been able to consult.

In 1893, however, careful observations were made at the World's Fair at Chicago by Mr. F. H. Chittenden, the results of which were published by Dr. Riley in Volume VI of Insect Life. Insects to the number of 101 species were found in grain and other stored vegetable products. Seven species were found affecting animal products and 13 wood-feeding species were found in the forestry building. The interesting and significant fact is mentioned in this article that there was an exchange of seed samples between the representatives of different countries, which would of course greatly facilitate the spread of seed-inhabiting insects, and it was further shown that thousands of samples were taken away from open bags by visitors from all parts of this country and probably from other parts of the world. Moreover, at the close of the Exposition the sheaves of cereals used in the decorations were taken away by armfuls by visitors. After summarizing the habits and countries of origin of the different species, however, Dr. Riley expressed the opinion that no dangerous importations were made at this time. It seems altogether likely, however, that Phyllotreta armoraciæ, a European species which has established itself in northern Illinois, Iowa and Wisconsin since 1893, and which was found by Mr. Chittenden in that year in vacant lots near the exposition grounds, was an exposition importation. Moreover, an interesting Carabid of the genus Tranes, the species of which are all Australian, has established itself injuriously in greenhouses in St. Louis as the result of the introduction of two plants of Zamia spiralis which were bought at the World's Fair. With these instances in mind we cannot but admit that other species heretofore overlooked probably escaped and have become acclimatized as the result of this exposition, and that such occasions, occurring as they do more and more frequently and drawing constantly increasing material from all parts of the world, will, unless precautionary measures are instituted, afford more and more frequent opportunities of a very favorable kind for the spread of injurious species.†

We have thus seen how great the opportunities are under our modern conditions for the transportation, in proper condition for establishment, of insects of many groups, and from this point of view it seems strange, in view of the very numerous importations, that more species do not become acclimatized even in North America, where, perhaps, we reach the greatest possibilities in this direction. Our most intimate commercial relations are with the great faunal region most like our own, and these relations are rapidly growing both with Europe on the east and with Asia on the west, although our Asiatic importations are more abundant from the Oriental region than the Palearctic, and from the Oriental we are not so likely to receive species which will acclimatize themselves. We have already pointed out that the faunistic relations with the Coleoptera (and undoubtedly with other groups) are least marked between the north temperate and south temperate regions, and this distinction is never likely to be disturbed by imported species on account of the diametrically opposed seasons. A species starting from Argentina in the height of summer will reach the United States in the dead of winter at a time least likely to favor its acclimatization. This point was first suggested by my colleague, Mr. E. A. Schwarz, in his paper entitled "The Coleoptera Common to North America and Other Countries." (Proc. Entom. Soc. Wash., I, 182-194.)

It appears from what we have shown that very many species are constantly being imported which do not become acclimatized. Many of the European species which we should most expect to take hold in this country have not done so, while with others it is the unexpected which has happened. As Osten Sacken says, speaking of the Diptera: "Importation will not occur for centuries in cases where it might be expected from day to day; and, again, it will sometimes take place under circumstances most improbable, and, à priori, impossible to foresee." (Proc. Entom. Soc. Lond., 1894, p. 480.)

Why should the well known Pieris rapæ have made its appearance in this country and spread far and wide, while the equally common and injurious Pieris brassicæ and P. napi have never been found here? Why should Phytonomus punctatus have flourished with us when it is hardly known as a clover enemy in Europe, and when the congeneric Phytonomus meles, of Europe, has never been found here? Why should Coleophora laricella have established itself here and none of the other European Coleophoras (some of them of much greater distribution and hibernating in cases of protective coloration and shape, and attached to plants) have acclimated themselves among us? Why should Calliphora vomitoria, Cyrtoneura stabulans and Stomoxys calcitrans have been brought over at an early date and flourished to excess in America and many other countries, while Sarcophaga carnaria is unknown in any of them?

Mr. Schwarz has phrased it: "We stand here before some great unknown factor, viz., the individual character and inmost nature of the species which governs the introduction or non-introduction of each species—a factor which is variable according to each species . . . ." But there is no reason why a mystery need be made of this condition. In a word, it is the capacity of the individual species to accommodate itself to a more or less novel environment. Nowhere in the whole animal kingdom do we find the natural environment more complicated than with insects. Conditions are frequently dependent upon conditions in an almost endless chain. The phenomena of fatal parasitism are of vital importance as determining the abundance of the species and are curiously complicated. I have recently proved the existence of several fatal tertiary parasites and the probable existence of quaternary parasites with Orgyia leucostigma in Washington. Upon the condition of this chain of interdependencies rests the welfare of the primary host. If adverse conditions affect the quaternary parasite, the primary host suffers, for the tertiary parasites increase and kill off the secondary parasites, allowing an increase of the primary parasites which kill off the Orgyia. The famous instance of Darwin in which he showed that in a measure cats are responsible for the production of clover seed in England through the interrelations of cats, field mice and bumble bees, is paralleled and outdone again and again among insects. Further, in no group of animals are the characteristics termed special protective resemblance and special aggressive resemblance, to say nothing of protective and aggressive mimicry, so well marked and so important in the life of the species as with the insects. It is upon the degree of simplicity of its life—the degree of simplicity of its normal environment as a whole—that the capacity of a species for transportation and acclimatization, even into a parallel life zone, depends.

Nevertheless, I am fully convinced that very many more species will stand transportation from the Palearctic to the Nearctic, from the Australian to the Oriental and the Neotropical regions, than would be supposed from a consideration of these points and from a knowledge of the comparatively few forms which have as yet been transported and acclimatized. Aside from the forms brought in with their food and thus under the most favorable conditions for establishment, it is only by a lucky chance with the average accidental insect immigrant that it finds conditions for reproduction—a chance which may not occur once in very many times. Osten Sacken has pointed out that Eristalis tenax must have been brought here many times during four hundred years before it succeeded in establishing itself. Undoubtedly many of these immigrants die upon our wharves when a lucky chance like crawling upon the clothes of a person and thus being carried out into the country might have resulted in the establishment of the species. Given the most favorable conditions, and many species will be able not only to accommodate themselves to a new environment, but certain of them will thrive better in the new than in the old. The effort to transport beneficial species from the Australian region and acclimatize them in the Nearctic region seemed a rash and unprofitable experiment on its face, and I confess that I for one had little hope of its success, yet it was successful with several species and transcendently successful with one.

Much has been written of late about the success of the work in the introduction of beneficial insects by Mr. Albert Koebele into Hawaii, under the auspices of the Hawaiian government. Some of the introductions seem, without doubt, to have been strikingly successful. Mr. R. E. C. Perkins has reported at some length upon this success and, in commenting upon its reasons, says:

"It becomes natural to ask why the success of the imported beneficial insects has been so pronounced here, while in other countries it has been attained in a comparatively small measure. The reason, I think, is sufficiently obvious. The same causes which have led to the rapid spread and excessive multiplication of injurious introductions have operated equally on the beneficial ones that prey upon them. The remote position of the islands, and the consequently limited fauna, giving free scope for increase to new arrivals, the general absence of creatures injurious to the introduced beneficial species, and the equability of the climate, allowing of almost continual breeding, may well afford results which could hardly be attained elsewhere on the globe. The keen struggle for existence of continental lands is comparatively non-existent, and, so far as it exists, is rather brought about by the introduced fauna than by the native one."

Mr. Perkins' reasons are all good, but he has not mentioned one prime reason of success, and that is that the most successful of the imported species have come from another portion of the same great faunal region, while others have been received from the region most closely allied, viz., the Oriental.

Wallace took the view that the effectual migration of insects is, perhaps, more than with any other class of animals, limited by organic and physical conditions. "The vegetation," he says, "the soil, the temperature and the supply of moisture must all be suited to their habits and economy, while they require an immunity from enemies of various kinds, which immigrants to a new country seldom obtain."

There is much truth in this statement, but it must be remarked that, in practical experience, immunity from enemies of various kinds is what insect immigrants find, not what they leave behind them. It takes some time before they weave into a new chain of organism preying upon organism. Our insect importations from abroad, when they are of economic importance—and those from Europe are very likely to be of such importance—leave their old insect enemies behind them and frequently are not readily attacked by native ones. These last accommodate themselves to the new comer in time, but for a while he enjoys comparative immunity. The rapid multiplication and spread of Pieris rapæ, of Hemiotobia serrata, of Phytonomus punctatus, of Porthetria dispar, of Anthonomus grandis, of Icerya purchasi and many others may probably be principally laid to this cause.

I should be remiss did I not refer to another aspect of the accidental introduction of species, viz., that it not only adds species to a native fauna, but also that it often causes the disappearance of native forms. Since the establishment, within our boundaries, of Pieris rapæ, our native Pontia oleracea has almost entirely disappeared in localities in which it formerly abounded, and in some sections has entirely disappeared. Since Doryphora 10-lineata came east and multiplied upon the cultivated potato in such prodigious numbers, the formerly common eastern Doryphora juncta has become a rare species. Walsh pointed out thirty years ago that one effect of the westward spread of the European Mytilaspis pomorum was to cause the gradual local disappearance of the native Chionaspis furfurus. Hubbard has shown that the increase of the imported Mytilaspis citricola in Florida was followed by the decrease of Mytilaspis gloverii, which, though not native, was an earlier importation—a most interesting, and, so far as records go, unique case. Instances might be multiplied which will show that the establishment of foreign species thus often produces at least a dual effect on the character of the fauna as a whole.

In closing it will not be inappropriate to point out that the accidental importation of species is only one of the ways in which the agency of man is altering the character of native faunas, and, that, in spite of its extent, it is really the least of the ways. The influence of civilization is immediately destructive to natural floras and faunas. It is already too late to gain an adequate idea of natural conditions in even recently settled portions of the globe. Wallace has dwelt upon the comparatively scanty and unimportant results to natural history of most of the great scientific voyages of the various civilized governments during the present century, from which it has resulted that "the productions of some of the most frequently visited and most interesting islands on the globe are still very imperfectly known, while their native plants and animals are being yearly exterminated. . . . Such are the Sandwich Islands, Tahiti, the Marquesas, the Philippine Islands and a host of smaller ones; while Bourbon and Mauritius, St. Helena and several others have only been adequately explored after an important portion of their productions has been destroyed by cultivation or the reckless introduction of goats and pigs." ("Island Life," p. 7.)

Elsewhere he shows that the introduction of goats into St. Helena utterly destroyed a whole flora of forest trees, and with them all the insects, mollusca, and perhaps birds dependent upon them. And further, that "cattle will in many districts wholly prevent the growth of trees; and with the trees the numerous insects dependent on those trees, and the birds which

* Paper read before the Zoological Section of the American Association for the Advancement of Science, August, 1897. A portrait of Doctor Howard will be found in the SCIENTIFIC AMERICAN of September 25, page 193.

† During the later months of the World's Fair precautionary measures were instituted under Mr. Chittenden's supervision. Much dry food material was fumigated with bisulphide of carbon, and many samples which were very badly infested were burned. At least four new and dangerous species of insects were destroyed in this way.

feed upon the insects, must disappear as well as the small mammalia which feed on the fruits, seeds, leaves or roots." Many local American instances have been brought together by Mr. F. M. Webster in an important paper entitled "Biological Effects of Civilization on the Insect Fauna of Ohio," which comes to me as I write these closing lines.

But the purpose of this address has been to dwell solely upon the question of the spread of species, and I must not touch upon other topics, however closely akin. It seems to me that the practical point to which we must come, after summarizing all that has been shown, is that since so many species have been imported by pure accident, and have succeeded perfectly in becoming acclimatized, may not much be accomplished by wisely planned and carefully guarded introductions? The somewhat haphazard but none the less important and skillful work of Albert Koebele, first for the United States government, afterward for the State of California, and now for the Hawaiian government, is certainly an indication, taken in connection with what we have shown, that thorough experimental work with predaceous and parasitic insects promises, in especial cases, results of possibly very great value.

We wish no more destructive birds like the English sparrow, we have no desire to make an American resident of the Indian mongoos, nor have we any desire to import the Australian flying fox as a pet. Neither do we desire to allow any more European plants to escape from cultivation and emulate the Russian thistle. But there are many absolutely beneficial insects of Palearctic regions which might flourish among us, and whose intentional introduction could not be harmful from any point of view, while they might be of the greatest service.

THE BRITISH ASSOCIATION—ADDRESS IN ANTHROPOLOGY.

THE address in Section H was delivered by Prof. Sir W. Turner, D.Sc., F.R.S. L. and E., who selected as the subject:

SOME DISTINCTIVE CHARACTERS OF HUMAN STRUCTURE.

THE EFFECT OF CLOTHES.

One of the requirements of civilization is the wearing of clothes, and fashion frequently prescribes that they should be tight-fitting and calculated to restrict motion in and about the spinal column. In savage races, on the other hand, clothing is often reduced to a minimum, and when worn is so loose and easy as in no way to hamper the movements of the body. The spinal column retains, therefore, in them much more flexibility, and permits the greater measure of freedom in the movements of the trunk which is found in savage man, and has often been referred to by travelers. It used to be considered that the possession of a lumbar convexity in the spinal column was the exclusive privilege of man, and was shared in by no other vertebrate. There can be no doubt that it attains a marked development in the human spine, and, as such, is associated with the erect posture. But the observations of Cunningham on the spinal column of apes, more especially the anthropoid group, made in fresh specimens, in which the intervertebral disks were in place, have proved that in the chimpanzee the lumbar convexity is probably as strongly pronounced as in the adult man. In a chimpanzee, two years old, the development is more advanced than in a child of the same age. The lumbar convexity is established at an earlier age than in the child, for it would seem as if the chimpanzee attained its maturity at a younger period of life than the human being. In the orang the lumbar curve is more feeble than in man and the chimpanzee, and in the specimen described by Cunningham resembled that of a boy six years old. In a fresh specimen of the gibbon, examined by the same anatomist, the lumbar curve was intermediate between the chimpanzee and the orang. Without going into the question whether a lumbar convexity exists in the tailed monkeys, the determination of which with precision is a matter of some difficulty, it must be obvious that the presence of this convexity can no longer be regarded as the exclusive prerogative of man. It undoubtedly forms an important factor in the study of the erect attitude; but in order that man should acquire and be able to retain his distinctive posture, something more is necessary than the possession of a spinal column with a curve in the lumbar region convex forward.

THE THIGH AND LEG.

Our attention should now be directed to the lower limbs, more especially to the two segments of the shaft, which we call thigh and leg. If we look at a quadruped, we see that the thigh is bent on the trunk at the hip joint, and that the leg is bent on the thigh at the knee joint; while the foot forms more or less of an angle with the leg, and the animal walks either on the soles of its feet or on its toes. In the anthropoid apes there is also distinct flexure both of the hip and knee joints, so that the leg and thigh are set at an angle to each other, and the foot is modified, through a special development of the great toe, into an organ of prehension as well as of support. When we turn to the human body, we find that in standing erect the leg and thigh are not set at an angle to each other, but that the leg is in line with and immediately below the thigh, that both hip and knee joints are fully extended, so that the axis of the shaft of the lower limb is practically continuous with the axis of the spine. The foot is set at right angles to the leg, and the sole is in relation to the ground. The vertical axis of the shaft of the lower limb, the extended condition of the hip and knee joints, and the rectangular position of the foot to the leg are, therefore, fundamental to the attainment of the erect attitude of man. As compared with the ape, the shaft of the human thigh bone is not so broad in relation to its length; when standing erect the shaft is somewhat more oblique, it is more convex forward and generally more finely molded, and it has three almost equal surfaces, the anterior of which is convex. But, further, a strong ridge (linea aspera) extends vertically down its posterior surface, so that a section through the shaft is triangular, with the two anterior angles rounded and the posterior prominent. In the gorilla, chimpanzee, and orang the shaft is flattened from before backward, and the linea aspera is represented by two faint lines, separated from each other by an intermediate narrow area. A section through the shaft approximates to an ellipse. In the gibbon the femur is greatly elongated, and the shaft is smooth and cylindriform. The linea aspera is for the attachment of powerful muscles, which are more closely aggregated in man than in apes, so that the human thigh possesses more graceful contours. In the human femur the shaft is separated from the neck by a strong anterior intertrochanteric ridge, to which is attached the ilio-femoral ligament of the hip joint, which by its strength and tension plays so important a part in keeping the joint extended when the body is erect. In the anthropoid apes this ridge is faint in the gorilla, and scarcely recognizable in the orang, gibbon, and chimpanzee, and the ilio-femoral ligament in them is comparatively feeble.

It may safely, therefore, be inferred that in apes, with their semierect crouching attitude, the ilio-femoral band is not subjected to, or capable of sustaining, the same strain as in man. The head of the thigh bone is also distinctive. In the apes the surface covered by cartilage is approximately a sphere, and is considerably more than a hemisphere. It is sharply differentiated from the neck by a definite boundary, and it has a mushroomlike shape. In man the major part of the head is also approximately a sphere; but, in addition, there is an extension outward of the articular area on the anterior surface and upper border of the neck of the bone. The form of this extended area differs from the spherical shape of the head in general. The curvature of a normal section of its surface has a much larger radius than the curvature of a normal section of the head, near the attachment of the ligamentum teres.

THE HUMAN FOOT.

I shall now proceed to the examination of the human foot (pes), and in order to bring out more clearly its primary use as an organ of support and progression, I shall contrast it with the human hand (manus) and with the manus and pes in apes. In man, while standing erect, the arched sole of the foot is directed to the ground, and rests behind on the heel and in front on pads, placed below and in line with the metatarso-phalangeal joints, the most important of which is below the joint associated with the great toe. It is, therefore, a plantigrade foot. The great toe (hallux) lies parallel to the other toes, and from its size and restricted movements gives stability to the foot. The ape's foot agrees with that of man in possessing similar bones and almost similar soft parts; but it differs materially as to the uses to which it can be put. Some apes can undoubtedly place the sole upon the ground, and in this position use the foot both for support and progression, though the orang, and to some extent other anthropoid apes, rest frequently upon the outer edge of the foot. But, in addition, these animals can use the foot as a prehensile organ like the hand. The old anatomist, Tyson, in his description of a young chimpanzee, spoke of the pes as "liker a hand than a foot" and introduced the term "quadrumanous," four-handed, to designate this character. This term was adopted by Cuvier, and applied by him to apes generally, and has long been in popular use. The eminent French anatomist was, however, quite alive to the fact that, though the pes was capable of being used as a hand, yet it was morphologically a foot, so that the term was employed by him to express a physiological character. In the ape the great toe, instead of being parallel to the other toes as in man, is set at an angle to them, not unlike the relation which the thumb (pollex) bears to the fingers in the human hand. It is able, therefore, to throw the hallux across the surface of the sole in the prehensile movement of opposition, as it can at the same time bend the other toes toward the sole. It also has the power of encircling an object more or less completely with them. By the joint action of all the toes a powerful grasping organ is produced, more important even than its hand, in which the thumb is feebly developed. It has sometimes been assumed that the human foot is also a prehensile instrument as well as an organ of support. In a limited sense objects can undoubtedly be grasped by the human toes when bent toward the sole. In savages this power is preserved to an extent which is not possible in civilized man, in whom, owing to the cramping, and only too frequently the distorting influence, exercised by badly-fitting boots and shoes, the proper development of the functional uses of the toes is impeded, and their power of independent movement is often destroyed. If we compare the anatomical structure of the human foot with that of the foot of the ape, though the bones, joints, and muscles are essentially the same in both, important differences in arrangement may be easily recognized, the value of which will be better appreciated by first glancing at the thumb. Both in man and apes the thumb is not tied to the index digit by an intermediate ligament, which, under the name of "transverse metacarpal," binds all the fingers together, and restricts their separation from each other in the transverse plane of the hand. The great toe of the ape, similarly, is not tied to the second toe by a "transverse metatarsal ligament," such as connects together and restricts the movements of its four outer toes in the transverse plane of the foot. The hallux of the ape is, therefore, set free. It can, like the thumb of man and ape, be thrown into the position of opposition and be used as a prehensile digit. Very different is the case in the human foot, in which the hallux is tied to the second toe by a continuation of the same transverse metatarsal ligament which ties the smaller toes together. Hence it is impossible to oppose the great toe to the surface of the sole in the way in which the thumb can be used, and the movements of the digit in the transverse plane of the foot are also greatly restricted.

THE HEAD.

The head, situated at the summit of the spine, holds a commanding position. Owing to the joints for articulation with the atlas vertebra being placed on the under surface of the skull, and not at the back of the head, and to the great reduction in the size of the jaws, as compared with apes and quadrupeds generally, the head is balanced on the top of the spine. The ligaments supporting it and connected with it are comparatively feeble, and do not require for their attachment strong, bony ridges on the skull, or massive projecting processes in the spine, such as one finds in apes and many other mammals. The head with the atlas vertebra can be rotated about the axis vertebra by appropriate muscles. The face looks to the front, the axis of vision is horizontal, and the eye sweeps the horizon with comparatively slight muscular effort. The cranial cavity, with its contained brain, is of absolutely greater volume in man than in any other vertebrate, except in the elephant and in the large whales, in which the huge mass of the body demands the great sensory-motor centers in the brain to be of large size. Relatively also to the mass and weight of the body, the brain in man may be said to be in general heavier than the brains of the lower vertebrates, though it has been stated that some small birds and mammals are exceptions to this rule. We have abundant evidence of the weight of the brain in Europeans, in whom several thousand brains have been tested. In the men, the average brain weight is from 49 to 50 oz. (1,390 to 1,418 grm.) In the women, from 44 to 45 oz. (1,248 to 1,283 grm.) The difference in weight is doubtless in part correlated with differences in the mass, weight and stature of the body in the two sexes, although it seems questionable if the entire difference is capable of this explanation. It is interesting to note that even in new born children the boys have bigger heads and heavier brains than the girls. Dr. Boyd gives the average for the girl infants as 10 oz. and for boys 11·67 oz. A distinction in the brain weight of the two sexes is obviously established, therefore, before the child is born, and is not to be accounted for by the training and educational advantages enjoyed by the male sex being superior to those of the female sex. The brains of a number of men of ability and intellectual distinction have been weighed, and ascertained to be from 55 to 60 oz. In a few exceptional cases, as in the brains of Cuvier and Dr Abercrombie, the weight has been more than 60 oz.; but it should also be stated that brains weighing 60 oz. and upward have occasionally been obtained from persons who had shown no sign of intellectual eminence.

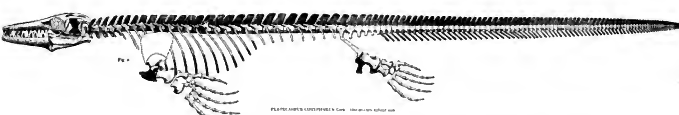
PHRENOLOGY.

The school of phrenologists represented in the first half of the century by Gall, Spurzheim, and George Combe, while recognizing the importance of the size of the brain as a measure of intellectual activity, also attached value to what was called its quality. At that time the inner mechanism of the brain was almost unknown, for the methods had not been discovered by which its minute structure could be determined. It is true that a difference was acknowledged between the cortical gray matter situated on the surface of the hemispheres and the subjacent white matter. Spurzheim had also succeeded in determining the presence of fibers in the white matter of the encephalon, and had, to a slight extent, traced their path. The difference between the smooth surface of the hemispheres of the lower mammals and the convoluted surface of the brain of man and the higher mammals, and the influence which the development of the convolutions exercised in increasing the area of the cortical gray matter, were also known. A most important step in advance was made when, through the investigations of Leuret and Gratiolet, it became clear that the convolutions of the cerebrum, in their mode of arrangement, were not uniform in the orders of mammals which possessed convoluted brains, but that different patterns existed in the orders examined. By his further researches, Gratiolet determined that in the anthropoid apes, notwithstanding their much smaller brains, the same general plan of arrangement existed as in man, though differences occurred in many of the details, and that the key to unlock the complex arrangements in man was to be obtained by the study of the simpler disposition in the apes. These researches have enabled anatomists to localize the convolutions and the fissures which separate them from each other, and to apply to them precise descriptive terms. These investigations were necessarily preliminary to the histological study of the convolutions and to experimental inquiry into their functions. By the employment of the refined histological methods now in use, it has been shown that the gray matter in the cortex of the hemispheres, and in other parts of the brain, is the seat of enormous numbers of nerve cells, and that those in the cortex, while possessing a characteristic pyramidal shape, present many variations in size. Further, that these nerve cells give origin to nerve axial fibers, through which areas in the cortex become connected directly or indirectly, either with other areas in the same hemisphere, with parts of the brain and spinal cord situated below the cerebrum, with the muscular system, or with the skin and other organs of sense. Every nerve cell, with the nerve axial fiber arising from and belonging to it, is now called a neurone, and both brain and spinal cord are built up of tens of thousands of such neurones. It may reasonably be assumed that the larger the brain, the more numerous are the neurones which enter into its constitution. The greater the number of neurones, and the more complete the connections which the several areas have with each other through their axial fibers, the more complex becomes the internal mechanism, and the more perfect the structure of the organ. We may reasonably assume that this perfection of structure finds its highest manifestations in the brain of civilized men. The specialization of the relations and connections of the axial fiber processes of the neurones, at their termination in particular localities, obviously points to functional differences in the cortical and other areas, to which these processes extend. It has now been experimentally demonstrated that the cortex of the cerebrum is not, as M. Flourens conceived, of the same physiological value throughout; but that particular functions are localized in definite areas and convolutions. It speaking of localization of function in the cerebrum, one must not be understood as adopting the theory of Gall, that the mental faculties were definite in their number, that each had its seat in a particular region of the cortex, and that the locus of this region was marked on the surface of the skull and head by a more or less prominent "bump." We have now direct anatomical evidence, based upon differences in the stages of development, that, in addition to the sensory and motor areas in the cortex of the human brain, a third division—the association centers—is to be distinguished. If we compare the cerebrum in man and the apes, we find those convolutions which constitute the motor and sensory centers distinctly marked in both. An ape, like a man, can see, hear, taste, smell, and touch; it also exhibits great muscular activity and variety of movement. It possesses, therefore, similar fundamental centers of

sensation motion, which are situated in areas of the cortex resembling in arrangement and relative position though much smaller in size than the corresponding convolutions in the adult human brain. It is not unlikely, though the subject needs additional research, that the miniature structure of these centers resembles that of man, though, from the comparatively restricted area of gray matter in the ape, the neurones will necessarily be much fewer in number. In the cerebrum of a new born infant, while the motor and sensory convolutions are distinct, the convolutions for the association areas, though present, are comparatively simple, and do not possess as many windings as are to be seen in the brain of a chimpanzee not more than three or four years old. The problem which has now to be solved is the determination of their function. Prolonged investigation into the development and comparative histology of the brain will be necessary before we can reach a sound anatomical basis on which to found satisfactory conclusions.

INSTINCT AND INTELLIGENCE.

We know that an animal is guided by its instincts, through which it provides for its wants and fulfills its place in nature. In man, on the other hand, the instinctive acts are under the influences of the reason and intelligence, and it is possible that the association centers, with the intermediate association fibers which connect them with the sensory and motor centers, may be the mechanism through which man is enabled to control his animal instincts, so far as they are dependent on motion and sensation. The higher we ascend in the scale of humanity, the more perfect does this control become, and the more do the instincts, emotions, passions and appetites become subordinated to the self-conscious principle which regulates our judgments and beliefs. It will, therefore, now be a matter for scientific inquiry to determine, as far as the anatomical conditions will permit, the proportion which the association centers bear to the other centers both in mammals and in man, the period of development of the association fibers, in comparison with that of the motor and sensory fibers in different animals, and, if possible, to obtain a comparison in these respects between the brains of savages and those of men of a high order of intelligence. The capability of erecting the trunk; the power of extending and fixing the hip and knee joints when standing; the stability of the foot; the range and variety of movement of the joints of the upper limb; the balancing of the head on the summit of the spine; the mass and weight of the brain, and the perfection of its internal mechanism, are distinctively human characters. They are the factors concerned in adapting the body of man, under the guidance of reason, intelligence, the sense of responsibility and power of self-control, for the discharge of varied and important duties in relation to himself, his Maker, his fellows, the animal world, and the earth on which he lives.



RESTORATION OF KANSAS MOSASAURS.

RESTORATION OF KANSAS MOSASAURS.

By S. W. Williston.

In the present communication are given restorations of the three principal genera of Kansas Mosasaurs, based upon the material now in the University of Kansas Museum. A detailed description of this material is now in preparation to be shortly published as a volume of the University Geological Survey, of which Chancellor Snow is director. At present only the more striking characters of the three forms will be discussed.

The three genera herewith given comprise all the authentic types known from Kansas. In addition, Holosaurus Marsh, Sironectes Cope and Baptosaurus Marsh have been described from or accredited to the Cretaceous of the State. Sironectes is, I believe, a synonym of Platecarpus. It was based upon the presence of the zygosphene in connection with free chevrons. In Platecarpus there is, in most species, a rudimentary zygosphene, and in some it is nearly as large as in some species of Clidastes. It is possible that Holosaurus is a good genus, but specimens of it must be exceedingly rare. The type specimen, now in the Yale Museum, was collected by myself and represents nearly the complete skeleton. Baptosaurus is practically known only from the posterior part of the jaw, described by Merriam. This is very peculiar in having the articular bone reflected upward at the extremity.

The material upon which the restorations here given are based is as follows: Clidastes is restored from a single specimen, complete in all details, save the terminal phalanges of the front paddle and most of those of the hind paddles. The present restoration differs from the one previously published only in the less flattened skull and in the curvature of the digits.

Platecarpus is based chiefly upon one specimen, comprising a nearly complete disarticulated skull and a connected series of vertebræ to beyond the middle of the tail, the sixty-fifth, together with the pectoral and pelvic girdles and most of the bones of the limbs. The arrangement of these bones has been copied, from Marsh, with some changes. The only parts conjectural are the number of long ribs and the number of chevron-caudal vertebræ. Isolated bones and partly connected series of caudal vertebræ are preserved in other specimens, from which there seem to be very slight differences from the corresponding parts of Tylosaurus. The tail has, therefore, been made to correspond with that of Tylosaurus in length.

Tylosaurus is drawn from three specimens, one with the posterior part of the head and the vertebral column complete to the tip, the second with the skull and cervical vertebræ in perfect preservation, the third with the paddles nearly complete, together with the larger part of the vertebræ and ribs. This last specimen is the one of which figures of the paddles and skin were given by me in a recent issue of this journal. All of these specimens agree closely in size and characters, clearly belonging to the same species.

A comparison of these genera, as shown by the restorations, will be of interest. Platecarpus has an intermediate position between Clidastes and Tylosaurus, which represent the extremes of development of the Kansas forms. In Clidastes the thorax is elongate, the tail relatively short and modified into a powerful propelling organ. The limbs are small, the hind ones especially so. The animal throughout is more slender, and the head relatively short, agreeing in this respect more closely with their nearest modern relatives, the species of Varanus. The vertebræ have the firmest and closest articulations, with the interlocking zygosphene best developed of any of the Mosasaurs. The limbs are less flexible, but relatively stronger, as shown by the closely articulating bones and the fully developed carpus and tarsus, and the more pronounced processes for muscular attachment. The movement through the water in this form was more snakelike than in the others, and propulsion was largely by means of the tail.

In Platecarpus we have the same shortened muzzle as in Clidastes, the vertebræ also relatively slender, and the zygosphene imperfectly developed. The paddles are more of the Clidastes type than that of the Tylosaurus, though the carpus and tarsus are less well developed than in the former. The hind paddles are only slightly smaller than the fore ones, and all are powerful propelling organs, far more so than in any other known genus of the group. Altogether, in proportion to its size, Platecarpus was the most powerful and predaceous of the Kansas Mosasaurs. It will be observed that the teeth in this form, while not as numerous as in Clidastes, or as stout as in Tylosaurus, are more effective weapons than in either of these genera, being more elongated, more curved and more pointed. The neural spines do not form as close a series as in Tylosaurus, indicating greater flexibility.

In Tylosaurus we have in some respects the most specialized of the Mosasaurs. The almost wholly cartilaginous carpus and tarsus, the more elongated digits and the greater number of the phalanges are characters brought about by aquatic habits. On the other hand, the hind paddle is actually larger than the front, and the fifth digit has undergone little or no reduction—characters of a more primitive rank. The paddles are more flexible than in either of the other genera, but they are relatively small and not at all strong. The skull is more elongated anteriorly and there is no trace of a zygosphene.

Dr. Dollo has expressed a doubt of the nature of the vertebræ called pygial by Mr. Case and myself in a former publication. He believes that some of them at least are true lumbar vertebræ, as all were previously thought to be. I feel yet more assured that they are basal caudal and have so restored the different genera. In the living lizard, with the sacral synchondrosis, the ilium is directed forward, throwing the symphysis ischii below the sacrum and leaving the outlet of the pelvis unrestricted. In Varanus there are as few as two non-chevron-bearing vertebræ back of the sacrum. More were not needed. In these marine lizards, on the other hand, the shaft of the ilium is directed obliquely forward, bringing the symphysis of the ischii below the fourth or fifth of the vertebræ succeeding the ligamentous attachment. If these or any of them bore chevrons, it will be immediately seen that they would project into the cavity of the pelvis. Not less than six pygal vertebræ are necessary to leave space for the free exit of the cloaca. The ilium must have been in every case attached to the first non-costiferous vertebra.

In these three species the number of vertebræ in the different regions may be given as follows:

	Clidastes.	Platecarpus.	Tylosaurus.
Cervical	7	7	7
Thoracic	11	13?	13?
Lumbodorsal	24	9	10
Pygal caudals	7	5	6
Diapophysial caudals	25	15	25
Non-diapophysial caudals	45	?	55

The zygapophyses in all three forms terminate at or near the end of the rib-bearing vertebræ. In the cervical region they are strong, diminishing but little in size through the thoracic region. In the region which I call lumbodorsal they become weaker. The vertebræ increase in length through the thoracic region, but diminish very rapidly in length at the end of the costiferous series.

The length of Clidastes velox is about twelve feet, that of Platecarpus coryphæus nearly fourteen, while Tylosaurus proriger, one of the smaller species of the genus, was over twenty-three feet. The smallest species of Clidastes, C. pumilus, if it be a distinct species, was about six feet in life. The largest species of the Kansas Mosasaurs, Tylosaurus dyspelor, had a length of nearly thirty feet. Only one other species of the group larger than Tylosaurus dyspelor has been described from America—Mosasaurus maximus Marsh, from New Jersey. If it had the same proportions as Tylosaurus, its length would be about thirty-two feet. If like Clidastes, as it was in all probability, its length would not exceed thirty-six feet. European forms somewhat larger than this have been described, possibly reaching a length of nearly forty feet. The text-books and popular descriptions place the length of these animals at from seventy five to one hundred feet.

The food of the Mosasaurs must have consisted chiefly of fishes of moderate size, with occasional victims of their own kind. While the flexibility and loose union of the jaws undoubtedly permitted animals of considerable size to be swallowed, the structure of the thoracic girdle would not have permitted any such feats of deglutition as the python and boa are capable of. The animals must have been practically helpless on land. They were not sufficiently serpentine to move about without the aid of the limbs, and these were not at all fitted for land locomotion. They lived in the open sea, often remote from the shores. Their pugnacity is amply indicated by the many scars and injuries they received, probably from others of their own kind.—Kansas University Quarterly.

MUMMIED HEADS.

HEREWITH are presented four cuts of very strange, post-mortem, artificially contracted Indian heads from Ecuador and Brazil. All have had the bones removed and are mummied to about the size of a large orange; are of slightly aromatic odor and leathery consistency.

The origin of these is somewhat mysterious. They are decidedly scarce, the few that have found their way into museums having for the most part been obtained in or about the town of Macas, at the foot of the

FIG. 1.

Andes—a town which does not at present have any direct intercourse with whites. Those from Macas appear to be larger than the few that have been derived direct from the Indians of the Jivaro tribe.

In the London Intellectual Observer of 1862 Bollaert, who draws his information from a history given by Velasco, says: "Heads of victims are cut off, the skull and its contents removed, and a heated stone introduced into the hollow of the skin. Desiccation goes on and it is reduced to about one-fourth, retaining some few of the features. . . . A double string is attached to the top of the head, so that it may be worn around the neck. The lips are sewn together and a number of strings hung from them, the use of which is not apparent."

In the Journal of the Anthropological Institute for 1874 Sir John Lubbock made the declaration—though upon what authority is not known—that "these heads are boiled for some time in an infusion of herbs, the bones then removed from the neck and heated stones put into the hollow, whereby the head is dried and contracted."

Dr. Page in a recent paper* states, on the strength

FIG. 2.

of "a distinguished anatomical authority in England," that if a dried preserved head be softened, boiled in water, and the bones removed by means of an incision along the occiput, the soft parts will shrink in exactly the same manner as the preserved Indian heads.

The same gentleman gives a list of such heads as he has been able to trace in the different museums of Europe. Besides six that were variously exhibited in London between 1853 and 1882, there are four in the British Museum; one in Brighton Museum; one at Owens' College, Manchester; three at Cambridge University; one in the Antiquarian Museum, Edinburgh; one in the Edinburgh University Anatomical Museum; one in Dublin University; three in Berlin University; three in the Public Museum of Vienna; three in the Vienna Pathological Museum. The editor of this journal has seen no less than four within the limits of the United States and one in Canada, all in private hands, though it is understood one of these has been donated to the Smithsonian Institution. Some of the heads described by Page do not, however, properly belong to this category, as they are of materially larger size, many containing a considerable proportion of the bony constituents, and the majority lack the thread ornaments which are the characteristics of those obtained from the Jivaros. It must be understood at once that the preserved heads from the East Indies, such as

FIG. 3.

are found among the Dyaks of Borneo and Sumatra, and likewise those derived from the Manchurucus of Brazil, are of entirely different character from these herein illustrated, and in great part retain their natural size.

Besides the list given by Page, we are informed there are several in Italian museums—four or five—and three at Madrid; there was also one—that probably pertains to the list given by Dr. Page—in possession of the late Dr. Frank Buckland, a facsimile of which appears in Fig. 1.

Of those brought to the United States, four were originally in the possession of Mr. Hassaurek, formerly United States minister to Ecuador, which the writer had the privilege of examining some years since. Mr. Hassaurek is authority for the information that these are not "worn about the neck," neither are they, as has been generally surmised, worshiped as household gods, but obtained by the Jivaros from the huacas or ancient burial places. While they are regarded with considerable reverence, no such superstition attaches thereto as has been commonly credited. It was a Dr. Andrade, curate of the village of Machuchi, who first propounded the idea that these heads were treated as idols, especially implored to keep family secrets, and for every secret intrusted a string drawn through the lips; he is to be credited also with promulgating the belief that they are worn by their possessors on solemn occasions as ornaments. All this is purely hypothetical, without any true foundation.

FIG. 4.

None of the heads seen by us have ever been opened upon the occiput, and only in one or two instances was there a cord through the sinciput for purposes of suspension.

It would seem highly probable that the threads that passed through the lips originally possessed some such significance as the Quippus of the ancient Peruvians, which are said to have been composed of large base cords, to which were fastened in a peculiar manner threads more or less fine and knotted or entwined in established order for the purpose of expressing ideas, events or numbers. The ancient Peruvians were in the habit of carving in semblance of human form the posts or wooden "idols" (?) which held these registers. The art or science of the Quippu language appears to have been lost to a great extent by modern Peruvians, although it is imagined there are in the southern provinces Indians who understand how to decipher these intricate memorials, but guard their knowledge religiously as a sacred secret inherited from their ancestors.

The configuration of the lips of these mummied heads, the perforations through them—which no doubt date from the earliest history of mummification—strongly suggests a purpose of chronicling history. Something of the same kind was observed of certain of the mummies that have been found of an extinct race that formerly inhabited the Fortunate (Canary) Islands.—The Medical Age.

ASTRONOMICAL WORK AT LICK OBSERVATORY.

By EDWARD S. HOLDEN, Director of Lick Observatory.

WHILE the resources of the Lick Observatory are large in comparison with those of many college observatories, they are very small in relation to those of the great establishments of Greenwich, Paris, Pulkova, Washington and Harvard College. For instance, the whole available income of the Lick Observatory for the coming fiscal year (exclusive of salaries) is $5,145. This sum must keep all the buildings painted and in repair; keep all our reservoirs and some five miles of underground pipes in order; provide for all painting, plumbing, brick laying, pipe fitting, carpenter work, machine work, etc., in the observatory and in the houses of astronomers and workmen; buy all supplies, such as lumber, hay, iron, brick, etc.; pay for all instrument making not done in the observatory; pay all freight, express and telegraph bills, maintain a telephone line 17 miles long in good order; pay for fuel, purchase books for the library; provide any needed apparatus for all the instruments, and, this year, buy much of the material needed for an eclipse expedition to India. It is no small task to make the small income cover the requirements. Every want which is felt in a large city is felt here. The circumstances at Mount Hamilton are as different as possible from those at Eastern observatories. There each person must provide for his own personal comfort; here the comfort of each one must be secured by the expenditure of the annual appropriation. If it is insufficient, every person suffers in some degree.

The astronomical efficiency of the Lick Observatory cannot be properly estimated without taking such material and social considerations into account. Under the circumstances, I do not think it is too much to claim that its efficiency during the nine years of its life has been satisfactory. This has only been attained by good will and earnest effort on the part of all concerned—regents, astronomers, mechanics, workmen. The summary of work for which you asked is given below.

Double stars have been measured here in past years in great numbers by Prof. Burnham, and at the present time Profs. Schaeberle, Hussey and Aitken are engaged in such work for parts of their time.

The satellites of Mars, Jupiter, Uranus and Neptune have been regularly observed here for the past nine years by Messrs. Schaeberle, Barnard, Campbell and Hussey. A fifth satellite of Jupiter was discovered by Prof. Barnard in 1892.

The planets, especially Mars, Jupiter, Saturn (and also Venus and Uranus), have been systematically observed for their physical features at every opposition by Messrs. Holden, Schaeberle, Keeler, Barnard and Hussey. For several oppositions of Mars the planet has been followed by Messrs. Holden, Schaeberle and Campbell during every available hour.

Comets have been discovered here in great numbers. Ten comets (seven unexpected) were discovered by Prof. Barnard from 1888 to 1892; five (four unexpected) by Mr. Perrine from 1895 to date. The long series of observations of these and other comets by Messrs. Barnard, Campbell, Hussey, Perrine and Aitken are a contribution to science even more important than the discoveries themselves.

Comet orbits have been computed here by Messrs. Schaeberle, Campbell, Hussey, Perrine and Aitken; and all comets discovered at the observatory have had their first orbits calculated by officers of the university. In this work Prof. Leuschner, of Berkeley, a former student here, and his assistant, Mr. F. H. Seares, have rendered assistance which is much appreciated.

Meteors have been observed and photographed here (and elsewhere) by all the astronomers, and their orbits calculated by Messrs. Holden and Schaeberle.

Double star orbits have also been computed by Prof. Schaeberle.

The zodiacal light was regularly observed (visually) by Prof. Barnard.

The aurora has been regularly observed (spectroscopically) by Prof. Campbell.

Typical or remarkable cloud forms are regularly photographed by Mr. Pauli, janitor of the observatory.

Nebulæ have been observed (visually, photographically and spectroscopically) by Messrs. Holden, Burnham, Schaeberle, Barnard and Campbell.

Star maps have been made and published by Mr. Tucker.

Photometry (photographic and visual)—of eclipses and of stars—has been attended to by Messrs. Holden, Schaeberle, Campbell and Leuschner.

Solar Eclipses.—Those of January and December, 1889, April, 1893, August, 1896, have been observed by Messrs. Burnham, Schaeberle, Keeler, Barnard, Leuschner and Campbell, and the latter will observe the eclipse of January, 1898, in India.

Lunar Eclipses.—All lunar eclipses visible here have been observed.

Occultations.—A series of occultations has been observed here by Prof. Leuschner.

Transits of Mercury.—Three transits of Mercury have been observed, either visually or photographically.

Transit of Venus.—That of 1882 was successfully photographed here by Prof. Todd.

Catalogues of Stars.—Two such are in progress of preparation.

1. A catalogue of double stars and of coast survey stars from observations by Prof. Schaeberle has been (partly) reduced, on lines laid down by myself, by Messrs. Schaeberle, Campbell, Leuschner, Aitken and Prof. Bigelow and Mrs. Updegraff. Prof. Aitken has spent more than a year on this work.

2. A catalogue of 28,000 stars from Washington observations is well toward completion. The reductions have been made chiefly by Messrs. Holden and Aitken. The original observations as printed were full of errors. The final places will be considerably more precise in declination and somewhat less precise in right ascension than the southern zones of Argelander.

Solar Photography.—Some 1,930 negatives of the sun (taken with the photoheliograph) have been secured by Mr. Perrine, and since April, 1896, some 450 more by Mr. Colton. Excellent experimental solar photographs on a large scale have been made with the 36 in. telescope, and it is hoped to go very much further with this work during the summer of 1897.

Lunar Photography.—A very full series of focal negatives has been made with the 36 inch telescope, chiefly by Messrs. Holden and Colton. An atlas on the scale of X feet to the moon's diameter has been prepared from these by Prof. Weinek, at Prague. Enlargements in the telescope have been made by Messrs. Holden, Colton and Perrine, and 5 plates of a moon atlas on the scale of 111 feet to the moon's diameter have been distributed. Twelve more plates are now in the hands of the engraver and will soon be issued; and about 20 more are ready to be published when the funds are available. The atlas will be complete with about 60 plates. All the work in the dark room was done by Mr. Colton.

Photographs of the Milky Way.—A great number of such pictures has been obtained by Prof. Barnard, who is preparing them for publication.

Photographs of planets, especially of Jupiter, have been regularly made by Messrs. Holden, Schaeberle and Colton.

Photographs of comets have been secured by Messrs. Barnard, Hussey and Colton.

Visual Photometry.—Two fine photometers of Prof. Pickering's design have lately been given to us by Miss Bruce. They will be used by Prof. Aitken, chiefly on double stars at present.

Spectroscopic observations of nebulæ, new stars, comets, stars and planets, have been made by Messrs. Keeler and Campbell. The chief problem of the great telescope is to determine the motion of the solar system by spectroscopic observations. It was first attacked here in 1888, and since that time it has been considered as our most important work. The results now attained by Prof. Campbell are of unexampled precision, and some of them will be published shortly. Many unexpected delays have occurred in this research, which has been under the charge of Messrs. Keeler, Crew and Campbell.

Time signals are sent out daily. Mr. Tucker is in charge of our clocks.

Meridian Circle Observations.—Mr. Tucker has completed a fine series of observations of all stars contained in any of the great ephemerides and not contained in the Berliner Jahrbuch. This work is all ready to print. He has also determined the places of a long list of stars used by Prof. Doolittle to determine the latitude of Lehigh University. The division errors of the 1° spaces of both circles of the instrument have been determined by Mr. Tucker with the assistance of Mr. Aitken.

Meteorological observations (tridaily) have been regularly made. They are now in charge of Prof. Aitken. A summary of all meteorological observations made here from 1888 to 1897 is in course of preparation by Mr. Perrine.

Earthquake observations are obtained on our two seismographs, which are in charge of Mr. Perrine. A complete list of all recorded earthquakes on the Pacific coast from 1769 to 1897 has just been prepared by Prof. Holden.

Publications of the Observatory.—The observatory has already issued three quarto volumes and five octavos, besides several pamphlets and the Moon Atlas. The Smithsonian Institution has lately published an octavo prepared here by Prof. Holden — Mountain Observatories—and will probably print his list of recorded earthquakes just mentioned. Notices from the Lick Observatory regularly appear in the publications of the Astronomical Society of the Pacific. More than 1,200 contributions to astronomical and other journals have been made by the officers of the observatory since 1888.

Trial of the Crossley Reflector.—This fine instrument, which had done such good work in the hands of Mr. Common, was presented to the Lick Observatory by Mr. Crossley in 1895. It was completely mounted in June, 1896, and given over to Prof. Hussey for trial. The work begun in 1896 is now being prosecuted. Photography in the Newtonian and principal foci will be tried by Prof. Hussey, and Prof. Campbell has a programme of spectroscopic observations to be carried on with the Bruce spectrograph (constructed here) in the principal focus. A powerful driving clock (the Bruce clock) has been made here from drawings by Prof. Hussey. It is essentially a copy, in little, of the Warner & Swasey clock of the 36 inch equatorial. Its conical pendulum weighs about 36 pounds.

The Schaeberle 18 inch reflector has been used for some years past in experiments in celestial photography by its maker, Prof. Schaeberle. Very interesting photographs of Jupiter have been obtained.

The Crocker photographic telescopes (a pair of Willard portrait lenses) will soon be mounted in a new dome near the Crossley reflector. A 12 inch mirror (by Prof. Schaeberle) of very short focus is to be mounted on the same stand.

Lick Observatory, July 7, 1897.

CHEMISTRY AND ARCHÆOLOGY.

THE fact that all the sciences are intimately allied, and that any one of them may be called upon to serve as the handmaid of any other, is once more exemplified by the services recently rendered to archeological research in France by some analyses made by the eminent chemist M. Berthelot, and described by him in the Comptes Rendus of the Academy of Sciences. By analyzing the metal of some early implements recently unearthed in Chaldea, he shows that they are pure copper—not bronze, as had been supposed—and throws interesting light on the methods and processes of metallurgy in those early times. The Literary Digest translates as follows:

"The discoveries made in Chaldea, at Tello, several years ago, by M. de Sarzec have made known to us monuments of great antiquity, going back to the origins of civilization, that is to say, five or six thousand years. They have furnished, among other things, arms, ornaments and utensils capable of throwing new light on the origin of the metal industries. Such are the objects deposited in the Louvre Museum, which M. Heuzey, my colleague, has submitted for my examination.

"I present herewith the results that I have obtained, which form a part of a methodical series of researches that I have been making for several years on the metals of ancient civilizations. The result has been a distinct advance in our knowledge of these interesting questions. In fact, we have here the earliest and most ancient records belonging to the copper age, whose date is definitely known."

The detailed results of a chemical analysis of various objects found in Chaldea are next given, and it is proved that such objects are practically pure copper, although many of them are labeled "bronze" in the museums. Says M. Berthelot:

"The existence of successive stages in the use and purification of metals, whether common or precious, follows from all these analyses. In particular, the employment of pure copper for making arms and utensils, even of current use, in Chaldea, about 4000 B. C., is established by the analyses. It preceded the use of bronze, that is of copper alloyed with tin, which is found in later objects, in Chaldea as in Egypt. We may even add that the form of doweled axes and the processes of manufacture, as well as the practical uses for which these utensils were destined, were the same for the pure copper axes of Chaldea as for the prehistoric bronze axes of Europe and Siberia. These observations appear to me the more worthy of interest, in that they are made on authentic objects that date in Chaldea and in Egypt from times that may properly be called historical—conditions not satisfied in the same degree by pure copper objects found in Europe. The discoveries made in Egypt and in Chaldea cast new light on problems that relate to the origin of metal industry in the history of the human race."

THE PATENT SYSTEM AS A FACTOR IN NATIONAL DEVELOPMENT.*

By WILLIAM C. DODGE.

THE question is sometimes asked: Is a patent system of benefit to a country? and not infrequently we find men and papers advocating the abolition of patents. Those who entertain such ideas generally belong to one of two classes—persons who confound modern patents with the "odious monopolies" of former times, and who think that inventions would be secured just as well without patents, and those who think that labor saving machines deprive men of employment, and are therefore injurious to the laboring classes.

This opposition has exhibited itself from the beginning down even to the present day. It is but a few years since a writer in a paper published at the capital of the United States asserted that "the invention of the steam engine and the sewing machine were among the greatest evils that ever befell mankind;" and it is a matter of history that in the same enlightened land prayers were offered in some of the churches that the wickedness of the newly invented sewing machine might be made apparent, and it makers be struck with a conviction that would induce them to stop its manufacture!

More recently an organ of a labor organization insisted that the introduction of patented machinery worked injury to skilled labor, as have also the leaders of some of these organizations, and writers in periodicals, during the past year.

It is to correct these erroneous impressions that I present the following facts.

If those who confound modern patents with the "odious monopolies" granted by the monarchs would but consider for a moment, they would see how erroneous such an idea is.

Under the old system of "monopolies," rights of which the public were already in full possession were arbitrarily taken from the public and conferred upon individuals, greatly to the injury of the public. For instance, Queen Elizabeth bestowed upon her favorites the exclusive right to sell steel, salt and other articles in the kingdom, the price of salt by the monopoly being increased from sixteen pence to fifteen shillings—over eleven hundred per cent.

On the contrary, a patent, instead of taking from the public anything which it already has, induces the inventor to spend his time, labor and money, and exercise his genius, in devising and giving to the public something new—something which it wants, and which, but for his invention, it might never have had. True, it gives him the exclusive right to make, sell, or use the invention, but only for a brief period, and that only upon the condition that he shall so illustrate and describe it that the public can make and use it at the expiration of his limited right, and thereafter have it free forever.

The difference between a modern patent and an old time monopoly is as clear and as distinct as the difference between day and night, and there is no excuse for their being confounded by any intelligent person. In fact, it was to abolish and prohibit the "odious monopolies" that the patent system was established.

In no part of the world have inventions been so extensively made and used as in the United States, and there can be no better way of determining whether the patent system has been beneficial, and whether or not it is for the public good to continue it, than to consider what it has done for that country.

To get an idea of what has been accomplished during the first century of American existence under the patent system, let us briefly compare the condition of the United States in 1790 with that of 1896.

Their territorial area has increased from 830,000 square miles to 3,314,230; their population from 4,000,000 to more than 70,000,000; their 75 post offices to about 70,000; and their 1,500 miles of postal routes to nearly 500,000 miles, on which there is a travel of 409,398,425 miles—enough to encircle the globe more than 16,000 times! In 1790 they had practically no manufactures. At the close of the revolution their manufactures amounted to only $20,000,000, the total product as late as 1830 being but $80,000,000; while in 1890 their manufactured products amount to almost $9,250,000,000—far more than those of Great Britain, and more than one-third of the total manufactured products of the world. At the same time their agricultural products have grown to the sum of $4,500,000,000 per annum.

In 1790 such things as steamboats, railroads, telegraphs, and telephones were unknown, while now the United States have 181,000 miles of railroad, with a total trackage of 221,000 miles, giving employment to about 800,000 persons.

The street and suburban railways aggregate nearly 40,000 miles, of which nearly one-third are electric roads, with 30,000 motor cars.

On the 15,000 miles of Western navigable rivers and 95,000 square miles of lake surface there are 2,705 steamers, with a tonnage of 806,584 tons, while the craft on these inland waters number 10,237, with a tonnage of 4,319,734 tons. The traffic on the great lakes alone amounts to nearly 40,000,000 tons. During the eight months of navigation 60,000 vessels pass through the Detroit River, with a tonnage of over 36,000,000 tons. The tonnage of entrance and clearance of the two ports of Chicago and Buffalo exceeds that of any city in the world, except London, and very nearly equals that (London, 20,902,534; Chicago, 10,288,868; Buffalo, 9,500,500). From the single port of Escanaba, on Lake Michigan—a place so young as to be unknown abroad, and known to but few at home—there were shipped in 1892 nearly 4,000,000 tons of iron ore and 120,000,000 feet of lumber, her tonnage being more than half of that of Liverpool, which is excelled only by that of London.

The United States produce now more iron ore and manufacture more iron and steel than Great Britain, which heretofore has led the world in that line. They have 800,005 miles of telegraph wires, with 25,000 stations, independent of ocean cables, and 440,730 miles of telephone wires, with more than 500,000 instruments in use.

But, wonderful as these statistics show the growth of the country to have been, they do not tell the whole story; for it must be borne in mind that in 1790 the four millions of people were scattered mostly along the Atlantic seaboard in sparse settlements. Moreover, it must be remembered that this small number of settlers had the whole continent to subdue—forests to clear, farms to open, houses, roads, bridges, schools, and churches to build, in fact, everything to create, with the savages to contest every foot of advance—and that the western continent had neither the accumulated wealth nor the surplus labor of the old world with which to accomplish this gigantic task. But even that is not all, for, in order to get a clear idea of the conditions under which the United States began existence as a nation, one must consider also the restrictions placed upon the colonists by the mother country.

The policy of the mother country from the very first was one of suppression of all manufacturing industries. As early as 1621 an order of the king and council prohibited the shipment of tobacco or any other production of the colonies to any foreign port, except to be first landed in England, and a duty paid on it there.

This policy was continued even after American independence, and various acts, from 1781 to 1790, were passed, prohibiting under heavy penalties the shipment from Great Britain of "any machine, tool, engine, press, paper, utensil, or any part thereof, or any model or plan thereof, which was, or thereafter might be, used in the manufacture of woolen, cotton, linen, or silk manufactures," and also prohibiting the shipment or enticing away of any artificer or workman in these several branches; and in 1795 this act was made perpetual.

It was not until 1825 that the restriction upon workmen leaving the country was repealed, and that upon machinery not until 1845.

The object of all this, as stated in the preamble to the act of 1763, was "the keeping of his majesty's subjects in the colonies in a firmer dependence," "the increase of English shipping," and "the vent of English manufactures." The idea and purpose of the British government in reference to the colonies was succinctly stated by Sir Robert Peel, when he said: "It is the destiny of the United States to feed Great Britain, and the destiny of Great Britain to clothe the United States."

Of course, under such control by the mother country, the colonists could engage in nothing but farming and the production of raw material, to be shipped to England for the use of her manufacturers.

During the revolution manufactures were established to partly supply home needs, but with the close of the war a reaction set in that soon destroyed most of them. Under the confederation of the colonies, which was solely for common defense, the general government had no power to grant patents, or to regulate commerce, or to impose duties on foreign goods, those rights being exercised by each colony or State as it saw fit. Massachusetts, New York, and those most interested in commerce, imposed no duties, and the result was that, in a year or two after the close of the revolution, the country was so flooded with the cheap products of England and other countries as to break down all the manufactures that had been established during the revolution and bankrupt the merchants. So terrible was the condition of affairs that petitions were sent to Congress asking it to issue "fiat" paper money, and loan it to the people. In Pennsylvania the State government actually did this.

It was this condition of affairs which finally resulted in the constitutional convention in 1787, which conferred on Congress the powers under which the country has since grown to its present estate. Among the powers conferred on Congress by the Constitution, two of the most important, so far as national prosperity and growth are concerned, are the power to regulate commerce and impose duties on imports and the power to provide for the grant of patents. These may well be termed the right and left arms of American growth

* From a copyrighted article in the Engineering Magazine, republished by permission.

and prosperity, and it is a question which, after all, is the right arm and which the left. Under the exercise of those two powers, for the first century of existence, the United States have so grown and prospered that they now do one-third of the world's manufacturing, one-third of its mining, and one-fifth of its farming, and possess one-fifth of its wealth. And, best of all, this is the result of peace and the intelligent application of the arts.

Now, what has caused this marvelous growth? Doubtless there are several causes. The cheapness of a virgin soil and free institutions inducing immigration from abroad were two of the causes; but these alone do not account for it.

By some it is contended that the tariff has been the prime cause of American prosperity. Without desiring to discuss that or any political question, and admitting that a tariff is necessary for national revenue, and that it has been, and is, of importance to the manufacturing interests of the country, I assert, without fear of successful contradiction, that the patent system of the United States has been, and is now more than ever, one of the prime causes of national growth and prosperity.

As stated by Commissioner Leggett in his report for 1878, from three-fourths to nine tenths of all American manufacturing is based, directly or indirectly, on patents; that is to say, the people are engaged in manufacturing patented articles, or are using patented machines and processes to manufacture articles not patented.

One need but step into any shop where articles are being produced—from the saw mill in the woods that now cuts its 300,000 feet per day to the little shop in the attic where toys are produced, or the great factories turning out their millions' worth of articles of every variety—to prove the truth of this statement. In fact, you cannot touch a thing anywhere, in the shop, on the farm, in the household, or the office, that does not bear the impress of patented inventions.

But to show that this is not merely an individual opinion, let me quote what an intelligent Englishman says on the subject. Harris Gastrell, secretary of the British Legation, in a detailed report a few years since to his government upon the industries of the United States, says:

"I cannot close this report without recording the fact that, in every important branch of industry referred to in the course of the previous pages, the American manufacturers seemed to be ever gaining on their competitors of the old world by availing themselves to the utmost of every advantage of improved process or labor saving machinery which American or other inventors may offer.

"There can be little doubt but the celerity with which all such advantages are thought out and then introduced into general use is owing to the constant pressure of high rates of wages and the comparative certain protection of capital invested in inventions.

"Neither can I close without observing how favorably the great industries of the United States would probably compare with the best organized of the competing industries of Europe. The past history and present development of the textile (and metal) industries is an earnest of a prolific future. Whether or not a reduced cost of living shall ever be attained, I cannot doubt that, under sound conditions of production, American industry will not only supply its own market, but will also become a formidable competitor in foreign markets in many articles.

"How soon that competition abroad may take place in this or that industry is not for me to conjecture. But I think that the data in this report are sufficiently full and correct to enable others to predict that time in respect to the cotton and woolen industries."

At a meeting of the British Association, after his return from the Philadelphia Centennial Fair, Sir William Thomson said:

"I was much struck with the prevalence of patented inventions at the exhibition; it seemed to me that every good thing deserving a patent was patented. I asked one inventor of a very good invention: 'Why don't you patent it in England?' He answered: 'The conditions are too onerous.' We are certainly far behind America's wisdom in this respect. If Europe does not amend its patent laws, America will speedily become the nursery of inventions for the world."

Mr. Hulse, the English judge of textiles, in his report to Parliament, said:

"The extraordinary extent of ingenuity and invention existing in the United States and manifested throughout the Exposition I attribute to the natural aptitude of the people, fostered and stimulated by an admirable patent law system."

So, too, the Swiss commission were so impressed by what they saw at Philadelphia that they published an address to their manufacturers, in which they told them that their only hope was in the adoption of a patent system; and the result was that Switzerland in 1888 adopted a patent law.

The United States consuls, in their reports to the State Department on the effect in Europe of the Centennial Exhibition in 1876, show how American implements and products were being preferred in Europe, especially agricultural machines and tools; and Consul Winser gives long extracts from a book published by Dr. Herman Grothe, a prominent German political economist, who visited the fair for the sole purpose of "studying the principles which had operated so powerfully in bringing about this rapid and high development of American industries," and who lays great stress on "the stimulating effect of the patent laws."

Dr. Grothe further says:

"Moreover, owing to the use of labor saving machinery and finer and better adapted tools, the cost of manufacture, in spite of higher wages in the United States, is lessened to the point where competition with other nations in supplying foreign markets may fairly be tried; and there can be no doubt that a great many lines of American wares will eventually find ready sale in the German market, in some cases to the exclusion of the same classes of goods of English, French and even home manufacture. All this is granted."

In the reports of the British commissioners to Parliament it was stated that, "as regards extent of invention and ingenuity, the United States was far ahead of other nations;" that "a great part of the marked advance in the improvement of workmen's tools which has been made during recent years is justly due to the inventive genius of American citizens;" that "one cannot fail to notice the great fertility of invention displayed in America;" that "there is great inventive power, and a ready and fearless adaptation of the means to the end sought;" that "no one could fail to be struck with the great and successful application of science to useful purposes in America;" and that, "judged by its results in benefiting the public, both by stimulating inventors and by giving a perseveringly practical turn to their labors, the American patent law must be admitted to be the most successful, and the beneficence of its working was very amply illustrated throughout the American region of the Exhibition."

Edward Bally, one of the Swiss commissioners, said: "I am satisfied from my knowledge that no people have made, in so short a time, so many useful inventions as the Americans; and if to-day machinery apparently does all the work, it nevertheless by no means reduces the workman to a machine. He uses a machine, it is true, but he is always thinking about some improvement to introduce into it, and often his thoughts lead to fine inventions or useful improvements."

As a result of these obvious facts, a committee of the British Parliament some years ago, after two years of investigation, recommended the adoption of the American patent system, and again in 1894 the subject was agitated. Norway and Sweden in 1885, Canada in 1886, and Germany in 1888 adopted a similar system of preliminary examination, and now they grant patents only for what is new and original. Thus the foremost manufacturing nations of Europe recognize the superiority of the American patent system, and make acknowledgment of its beneficial results.

Now, when the United States manufacture more than they consume and seek other markets for a surplus of both manufactured and agricultural products, the patent system more than ever becomes important; for, with higher priced labor and raw material, how are goods to be made there, and sold in Central and South America, in open competition with the cheaper labor and cheaper raw material of England, France, Belgium and Germany? If the cost of both labor and material could be reduced to a European basis, then, of course, America could compete; but that can not be done, for the price of labor cannot be fixed by law, nor would the United States want to reduce it, if it could. That was tried in England, and also in New England, and abandoned centuries ago.

The main hope is in inventions and the skill and energy of the American people. If inventors can furnish manufacturers with improved machines and processes, which will reduce the cost of production from fifteen to twenty per cent., then the new world can compete with the old world; otherwise not. Already that point is rapidly approaching, as the following facts show:

In 1850 the manufactured products of the United States amounted to but	$90,848,210
By the census of 1850 they had grown to ..	1,019,106,616
" " 1860 " " " ..	1,885,861,676
" " 1870 " " " ..	3,385,860,354
" " 1880 " " " ..	5,369,579,191
" " 1890 " " " ..	9,224,541,091

Or, according to Mulhall, more than one-third of the total manufactured products of the world!

This remarkable increase has been largely, if not mainly, due to inventions, stimulated and fostered by the patent system. As proof of this I cite the fact that the amount per hand employed has constantly increased. For instance, as shown by the census reports, in 1850 the product per hand, yearly, was $1,564, while in 1890 it had grown to $2,250—an increase of nearly 44 per cent. in forty years. During that time the hours of labor have been reduced at least 20 per cent., and yet the product per hand has increased, as above shown. Nor is this all, for, while the hours have been decreased, and the product increased, the wages paid those hands have increased in even greater ratio, or from an average of $247 per year in 1850 to $450 in 1890, an increase which is even further augmented if measured by the purchasing power of a dollar then and now.

Now, how is it, and what is it, that enables an operative to-day to produce so much more, in a less number of hours, than he could thirty or forty years ago? It is simply invention, as embodied in the improved machines, tools, processes and appliances that American inventors are constantly furnishing to American manufacturers.

Near Baltimore there was recently erected one of the largest plants for the manufacture of Bessemer steel in all its forms in the world; and, as recently stated by its superintendent, by means of the inventions and improved appliances they have adopted they are enabled to produce a ton of steel with but one-third of the manual labor required at their other establishment, built twenty or twenty-five years before.

In 1866 steel rails cost $165 per ton. In 1884 they had dropped to $34, in 1893 they were $21 to $24 per ton, and in 1897 even less. See how that has expedited the building of railroads, which now cover the country like a network, and without which modern existence could not be carried on. And the same is true of steel in all its forms, so that to-day we build steel bridges, steel vessels, steel cannon, steel frames for our buildings, and for farm implements, and use steel nails.

Inventions and improvements have so reduced the cost of steel rails that already, during the year 1897, the United States have sold 100,000 tons to Europe. They sold 100,000 tons of pig iron from the Southern States in 1896, and this year it is estimated that it will be 250,000 tons, where before the war none was produced. In 1896 the American export of iron and steel, manufactured and unmanufactured, amounted to over $11,000,000.

As an illustration of the benefits of invention, take the common nail. In 1818, when they began to be made by a machine operated by hand in Pennsylvania, they cost from 18 to 37½ cents per pound, according to size. Now they are sold at 1 to 1¼ cents per pound—so cheaply indeed that a carpenter, working for 30 cents an hour, had better let a nail go than to spend ten seconds to pick it up, for ten seconds of his time is worth more than the nail!

In a report made by the United States consul at Birmingham, he cites a paper prepared by an English expert, who forcibly describes the danger from American competition to the British manufacturer of steel.

That is the result of invention. And the same is true of nearly all branches of manufactures. Says the Iron Industry Gazette:

"Disparagement of patents is common and easy, but it should not be forgotten by those who sneer at inventors that, out of a total of over $8,100,000,000 of capital invested in manufacturing in the United States, patents form the basis for the investment of about $6,000,000,000. Evidently, the United States system of encouraging invention that has resulted in the patenting of over 540,000 inventions is a system that is exceedingly wise and valuable. The one thing that has enabled manufacturers to make so wonderful a progress in the United States is its patent system."

PHYSIOLOGICAL EFFECTS OF MENTAL WORK.*

WITHIN the present decade the relation between mental work and the bodily processes has been the subject of much study. Interest in the problem as a field for practical inquiry was first aroused by a paper on the fatigue resulting from intellectual work, published by Sikorsky in the Annales d'Hygiène Publique for 1879. He was followed more than ten years later by Burgerstein, Laser, Griesbach and others. In these investigations the method used was that of testing school children in classes. Various problems and exercises were set before them, during and after the school session, and the percentage of errors committed in the operations was taken as measure of the fatigue due to mental work. While some individual errors might be due to other causes, the average percentage of the entire class seemed a fair test of this factor. The latest instances of this method are the investigations of Friedrich and Ebbinghaus, described in the May number of the Naturalist. At about the same time Mosso and his pupils took up the question from another side. They instituted a series of laboratory investigations upon single individuals by means of the ergograph, with a view to determining the fatigue due to steady intellectual as well as physical work. Kraepelin and his pupils meanwhile undertook the same problem, varying it with tests of the influence of various stimulants and narcotics on the capacity for mental work. They made use of the reaction time method, as well as the percentage of errors. More recently, Binet and his pupils have taken up the subject from a different standpoint, their object being to measure the effect of mental stimulation and mental effort on the bodily processes of breathing, heart action, etc. Several other investigators have studied the problem in one or other of these forms. Among them may be noted Féré, Patrick and Gilbert, Frey, Bolton, Bergström and Henri.

In an article in the Année Psychologique for 1896, M. Henri gives a résumé of the various investigations and the methods used in each. He emphasizes the importance of distinguishing the different factors involved in both mental and physical work, and of studying each one separately by appropriate experimental methods. Among these factors he specifies in particular attention, voluntary effort, the psychic processes of memory and imagination. Little progress has as yet been made in the way of investigating effort, except in the study of pathological cases, such as aboulia. As for attention, while considerable work has been done in this field, the investigations have generally had for their end to determine the mental effects of fatigue and other variations in the conditions, rather than to measure the physical effects of variations in the attention. Memory has been, perhaps, more systematically studied than any of the other factors.

The investigation of the effect of intellectual work on the pulse and other functions which MM. Binet and Courtier have undertaken seems most likely, of all methods so far devised, to furnish a measure of psychical work in physical terms. A series of papers on the subject by these authors has appeared in the Année Psychologique, the first in the issue for 1895 and four others in the last volume.† In approaching the question it was first of all necessary to study the effect of changes in respiration on the heart beat and blood supply. A large part of the first paper is accordingly taken up with this and with an examination of possible errors in the apparatus. The instrument used was the plethysmograph of Hallion and Comte. This consists of a rubber cylinder, which is grasped firmly by the hand. The outer surface of the hand is covered with a tight-fitting glove, so that any expansion in volume of the hand (due to increased blood pressure) takes effect on the inner surface, and results in diminishing the volume of the rubber cylinder. The latter communicates by means of a tube with a flexible drum. When the cylinder is compressed by the hand the drum rises, and the effect is recorded by means of a pen attached to the drum. The apparatus was found to be very serviceable, and was remarkably free from error. In addition to the frequency and strength of the pulse beat, the dicrotism, or break in the beat, was clearly marked in the diagrams, and proved an important factor in the results.

MM. Binet and Courtier note the existence of important individual differences in the effects of mental work on the physical processes. In some subjects these are confined almost wholly to changes in the respiration, in others to the action of the heart, while in others they are felt more especially in the vaso-motor system. In general, the effect on the respiration is to make it more rapid and at the same time more superficial. The effects on the pulse curve most frequently observed are: 1st, diminution of amplitude; 2d, diminution of amplitude with change of form; 3d, diminution of amplitude, change of form and lowering of the level of the curve. One or other of these effects appears in almost all the subjects tested.

In their later papers the authors consider in turn the various causes of change in the pulse. They confirm the well known diurnal changes by numerous observations with their own method, e. g., that the pulse becomes more frequent and the dicrotism generally more marked immediately after a meal. As regards physical exercise, they lay special stress on the changes that occur in the dicrotism according as the exercise is local, general and moderate, or general and fatiguing.

The study of the effects of mental work is, of course, the most important from the psychological standpoint, and here the authors have sought to combine tests of

* The American Naturalist.

† Vol. III. 1896, published this spring.

the heart and respiration with those of the pulse. In addition to the more delicate tests, involving simple mental operations, two of the subjects undertook a piece of severe and prolonged mental work. They spent seven hours working steadily at this task, merely resting at the end of each hour for a time sufficient to perform the necessary tests. Comparing the results with those of a similar period passed under similar conditions but without work, the pulse was found to be considerably retarded in the former case, as compared with the latter, the retardation taking place especially in the early part of the period. The authors sum up their results on mental work as follows: "1. An energetic but short mental effort produces an excitation of function, vaso-constriction, acceleration of the heart and of the respiration, followed by a very slight retarding of these functions; in some of the subjects a blunting of the dicrotism. 2. Intellectual work lasting for several hours, with comparative immobility of the body, produces a retardation of the heart and a diminution of the peripheral capillary circulation."

As regards the relation between physical and mental work, the authors are cautious in drawing conclusions. They observe a certain parallelism, in that a single energetic effort produces an acceleration of the heart and lungs, while a long-continued and fatiguing effort frequently weakens the dicrotism. On the other hand, the excitation of the heart is more marked and the acceleration of the respiration greater in physical than in mental work; again, in physical work the respiration grows deeper, while in mental work it becomes more superficial; and finally, prolonged mental work tends to produce a weakening of the peripheral circulation—an effect not observed in the experiments on physical work.

The effects of emotion on the heart and pulse are the topic of the last paper by the same authors. The experiments on this difficult problem were contrived with considerable ingenuity. Some of the subjects were children of from eight to ten, in whom it was easy to excite fear, surprise, pleasure, etc. With adults the tests had to be more carefully planned. A false alarm of fire was prearranged in one case, and resulted in real fear on the part of the subject. Another subject, after being blindfolded, had his hands placed on a pile of worms. A number of tests embodying various emotions were successfully made. It was found that every emotion tended to weaken the pulse. The quality of the emotion, whether pleasurable or painful, had no marked influence—the contrast was altogether between a state of mental rest and one of emotional disturbance. The heart showed a tendency to accelerate when the excitement was strong, and here too no difference was observable between the pleasant and the painful. The influence on the respiration was most marked of all. Every emotional excitement produced an acceleration and at the same time an increase in depth and a shortening of the pause.

The authors added a special study of the effects of music on these functions. Their experiments on this point were confined to one person—a man of fine musical appreciation and with considerable of a musical education. They represent, therefore, merely a single type of individual. There was found to be a distinct though slight quickening of the respiration and heart in consequence of hearing the tones themselves, and apart from any emotional "echo" aroused by them. When a melody was played, whether sad or gay, the acceleration was more marked, and it reached a climax when the piece was of a dramatic character and particularly fitted to arouse emotion. This acceleration, however, was not accompanied by any noticeable irregularity. There was at the same time in general a weakening of the capillary circulation, which was less when the sounds had merely a sensorial effect than when they produced a distinct emotional disturbance.

In summing up the whole question of emotional effects on the bodily functions, the authors again lay stress on the differences among individuals. From their own observations they are inclined to distinguish three separate classes of effects. 1. In a majority of persons every emotion produces a vascular constriction, an acceleration of the heart and of the respiration, and an increase of amplitude in the thoracic cavity. 2. In some few cases a sensation of pain or an emotion of sorrow may produce a slight retardation of the heart. And 3. It is possible, as observations made on one subject prove, that the form of the capillary pulse may change with the quality of the emotion; this last effect, they remark, may in time enable us to make a classification of the emotions according to their physiological effects on the form of the pulse.

PREVENTION OF THE SLIDING FRICTION OF BALL AND ROLLER BEARINGS.

WHEN two parts of a machine displace themselves, one with respect to the other, to a circular motion, their friction develops stresses which are variable and which have the effect of absorbing a very appreciable part of the work developed by the motor. Such, for example, is the case with the pillow blocks supporting a revolving shaft. However carefully the lubricating be done, and whatever be the value of the lubricator employed, such frictions are inevitable: the pieces in contact wear irregularly, and, in the long run, there occur flattenings that still further increase the resistance to be overcome. It is for this reason that bearings are provided with linings of soft metal, bronze or regulus of antimony, which support all the wear and are easily replaced.

General Morin's experiments have permitted the fact to be recognized that under proper conditions of manufacture and lubrication, the coefficient of the sliding friction of a shaft in its bearings is 0·054.

In calling T the work absorbed by friction, P the stress exerted, C the path traversed, and F the coefficient of friction, the value of T is given by the formula:

$$T = P \times C \times F.$$

It will be seen from a simple inspection of this formula that the work absorbed by friction is so much the less in proportion as the coefficient of friction is less. An endeavor has, therefore, naturally been made to find a means of substituting rolling friction, the coefficient of which is much less (0·001, according to Poncelet), for sliding friction. Were such substitution perfectly realized, it will be seen that in this second case the friction would be 54 times less than in the first. But in practice we are far from reaching such a result. In fact, roller bearings and ordinary ball boxes with cells, perforated disks, superposed rings, etc., only partially suppress sliding friction, a notable part of which is simply displaced, as may be easily seen from an inspection of Fig. 1.

Let A be a shaft revolving in the direction shown by the arrow and bearing against a series of rollers, B. Through the motion of the shaft, these latter will revolve in a direction opposite that of the latter and will rub against each other at their points of contact, a, since at such points each will revolve in a direction opposite that of the other.

As may be seen, the addition of the rollers has no other result than that of transferring to the points, a,

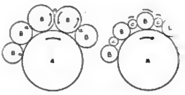

Fig. 1 Fig. 2

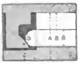

Fig. 3

the sliding friction that was developed previously upon the circumference of the shaft, in diminishing it, it is true, but without suppressing it. In fact, calculation shows that by the substitution of ball or roller bearings for smooth ones, the saving in the work of friction reaches, at a maximum, 40 per cent. And yet this figure diminishes rapidly as a consequence of the wear that is inevitable, even with the use of pieces of steel, tempered and trued after tempering.

In order to obviate the sliding friction of rollers, B, M. G. Philippe has conceived the ingenious idea of isolating the rollers from each other by means of intermediate and smaller ones, C, which revolve in a direction contrary to that of the first, that is to say, in the same direction as the shaft, A.

A simple inspection of Fig. 2 will show that there is a rolling friction at the points of contact of the rollers, B and C, as well as between the rollers, B, and the shaft, A.

We have here supposed a case of rollers, but it is evident that the results will be the same when balls are employed. The sole condition to be realized is to select the diameters of the large and small balls in such a way that the paths traversed shall be equally proportional.

Fig. 3 supposes a case in which the axis, O, in revolving, carries along the large balls, B, which roll in the compartment, A, and communicate their circumferential velocity to the small intermediate balls, H. The latter are kept in place by means of a path, C, upon which they rest by their extremity, D, and which is cast in a piece with the chamber, A. In order that the paths traversed shall be equally proportional, the diameters of the elements must satisfy the following equation:

$$\frac{B}{A} = \frac{C \times H}{B \times D}$$

C and D are here the diameters of contact.

M. Philippe has studied various arrangements that permit of the application of his system to the most ordinary uses of mechanics. Figs. 4 and 5 give two arrangements of roller cages that may be applied almost without change to the present pillow blocks. In the fifth, the path, C, is connected with the bearing, A, while in the fourth it is connected with the shaft, O.

Fig. 6 gives the arrangement of a bicycle hub with ball bearings, the regulation of which is effected, as usual, by tightening the cone. The hub for light vehicles (Fig. 7) is, as may be seen, analogous to the preceding. These hubs for light vehicles will prove useful in automobile carriages, where, more than anywhere else, the necessity has made itself felt of suppressing friction in order that the motor may suffer no loss of power. When there are heavy loads to be supported, rollers rather than balls should be employed.

American electric tramway companies frequently

make use of roller bearings, but in employing the different ordinary systems of which the capital defect has been shown above.—La Nature.

A PORTABLE RECORDER FOR TESTS OF METALS.*

By Mr. G. C. HENNING, New York.

WHEN it is desired to know all about the working of a steam engine, to study the working of the steam valves, piston, clearances, etc., the indicator is used; this gives a record on rectangular co-ordinates of travel of the piston, and to the steam pressures throughout the complete cycle. Similarly, if it were possible to design an instrument like the indicator in its accuracy, portability, and universality, to record the behavior of materials from beginning to the end of the test, it ought to be of general utility for it, and its introduction ought to be comparatively easy. It should be complete in itself, readily and quickly applicable to all testing machines, and should be so constructed as to be readily examined for accuracy, and should, of course, be durable.

A great many recording instruments for stress-strain diagrams have been designed and used from time to time, but all have been found wanting in one or more respects, and not one has been made portable, so that engineers could take it from works to works and use it without first being compelled to make more or less costly mechanical preparation for its use in each case. Moreover, the instruments in almost every case are so costly that their general introduction and use became impossible, especially in view of their limited utility. Some of them, otherwise very ingenious, gave diagrams on circular co-ordinates which made them practically useless. Among apparatus used for this purpose may be mentioned those of Wicksteed, Unwin, Kennedy, Barr, Gray, Martens, Olsen, Mohr and Federhaff, and of Grafenstaden, but as they are fairly well known, it is not necessary to describe them in this paper. My conception of a practical recorder for testing materials is as follows:

It must be portable and compact, requiring no extra precautions in adjustment or regulation, and without having the accuracy of an instrument of precision, must be perfectly trustworthy, and as correct as the other apparatus in connection with which it is used. It must cover a wide range of work, of short and long, large and small test pieces, such as are found in general use, and must be applicable to hard and soft materials as well. The apparatus should be applicable in a horizontal as well as in a vertical position. Moreover, it should give a complete record from beginning to end of the test, showing the more important elements on an enlarged, and the lesser on a natural scale. Thus, while elongations within the elastic limit—yield point—are very minute, and must be recorded on a magnified scale which is trustworthy, changes of length beyond this critical point are very large, rapid, and variable; hence measurement with a steel scale suffices, and the record on a diagram may be on actual scale. This change of scale must, however, be positive, controllable, and at a fixed instant or point, and must not introduce errors in the record. In case of materials of slight extensibility, however, the entire record should be on one scale from beginning to end, and the instrument should be so attached that it does not nick or injure the material so as to affect its point of rupture or strength.

As materials under test change shape rapidly and constantly, the instrument must be so designed that this variation does not introduce errors by slipping or tilting or otherwise. Means must be readily applicable which will check the accuracy of the instrument at all times. As materials are generally tested at the present time, there is no lasting record of the qualities that are claimed to have been found. Moreover, it is well known that many properties of materials cannot be determined except by an autographic stress-strain diagram. The curves obtained vary according to the treatment which the material has been subjected to, and annealing or straining produces such marked results that an autographic record would at once indicate how the material has been treated. Hardening, cold rolling, tempering, and other processes are made apparent by the characteristic features of the curves. With the use of such a recorder, it would become instantly apparent whether material had been previously intentionally strained to raise the elastic limit, as is well known to have been done. Overheating of material would be clearly indicated by the change in the curve, and the general uniformity of any lot of material could be readily determined.

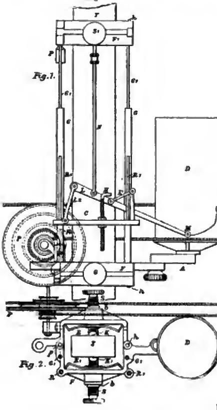
The instrument should also be applicable for compression tests, so as to record the behavior of material when subjected to compressive stresses. The engraving shows my design of such portable recorder, as based on the conception as explained. Two hinged frames, F and F_1, are provided with knife-edge pointed screw, S, passing through bushes, b, which carry springs, E. Hinge pins, h, allow the frames to open, while taper plugs, p, secure them rigidly together when closed around the test piece, T. In order that the knife edges, K, in the upper and lower frames, bear on the test piece, T, at given known distances, the guide rods, g_1, sliding in tubes, g, are made of a certain length. These rods, g_1, and tubes, g, cause the frames, F and F_1, to recede from or approach each other without changing their parallelism, and prevent any possibility of rocking of the lower frame, F, which carries the drum, D, on the arm, A. The drum, D, must remain at a uniform distance from the axis of the test piece throughout the test, as any change therein would vitiate the record materially, either increasing or reducing the apparent length of string, C.

The lower frame, F, also carries a parallel motion, G L, as in ordinary use in steam engine indicators. This parallel motion is actuated by the upper frame, F_1, through the connecting rod, N, which is interchangeable for longer or shorter pieces. The lever, L, of this mechanism carries a pencil or pen at m, which draws a line upon the paper wrapped on D, either horizontal when the drum is revolved, or a straight vertical line when the drum is stationary, and the frames, F and F_1, approach or recede from each other. If the drum revolve while the lever, L m, moves, any curve may be obtained according to their relative motions. As the possible change of length of material during test and up to the instant of rupture is very great, a very long drum would be required to record it on a magnified scale up to that point; the parallel multiplying motion would also become very large and cumbersome. Moreover, the change of length within the yield point is minute, and cannot be recorded to any purpose except on a magnified scale. Now, therefore, to record the elastic changes of length on a magnified scale, and the permanent changes on a natural scale, as the latter are never measured closer than to the nearest $\frac{1}{16}$ inch, I employ the following devices: The stop, H, arrests the multiplying mechanism at any desired point, after which it moves as a unit, and any further change of length is recorded on natural scale. To act as described, the parallel motion mounted on the bar, G, has two tubes, R, sliding on rods, R_1, the latter only being fastened to the frame, F. These tubes, R, are split, and can be made to grip the rods, R_1, with any necessary pressure.

It will be seen that the total maximum resistance to motion between frames, F and F_1, is the friction of tubes, g and R, on rods, g_1 and R_1, and friction of pen, m. As long as the motion is recorded on a magnified scale this resistance will be only the friction of rods, g_1, in tubes, g, of pen, m, and the resistance of the parallel motion. Therefore the total resistance will be minute, and not likely to affect the record in even the slightest manner by slipping of the knife edges and frames. The paper on the drum must move past the pen, m, at a rate equal or proportional to the motion of the poise weight on the beam. As loads are large or small according to size and quality of test piece, the poise must travel more or less to balance it. As it is desirable, however, to record all tests on the same sized diagram, the travel of the poise weight is reduced or increased by a grooved pulley, P, round any groove of which the string, C, tied to poise weight, is wrapped; the free end of this string carries a small weight to keep it always at the same tension. On any other groove of the pulley, P, another string passing around the drum, D, is wrapped, which is kept at the same tension by a small weight at its free end. By a proper selection of position of the two strings on the various grooves of the pulley, any desired rotation of the drum may be obtained.

Application of Instrument.—A light pulley is secured to the frame of the testing machine, over which the string, C, passes, the other end being attached to the poise weight, or to any mechanism moving in synchronism with it. A sheet of paper being mounted on the drum, the frames, F and F_1, are opened after the screws, S, have been so adjusted that the distances between the knife edges, K and K_1, are about $\frac{3}{8}$ inch less than the thickness of test piece. Then the frames are placed around the test piece, which has been placed in the machine, the frames are closed, pins, p, are inserted, the string, C_1, is passed around D, and C round the proper groove on P, while the poise weight is at 0—zero—and the test may begin. If it is desired to draw a base line for measurements of elongation, the drum is given one revolution while the pen bears against the paper; it is not necessary—though it can readily be done—to draw the other axis to the base line, as the motion of the pen is always at right angles to it. If it is desired to mark the scale of loads on the base line, all that is necessary is to revolve the drum by running out the poise to the several load points, and then making a mark for each of them. Once this scale is determined, it will be the same in all work.

In the case of materials with very slight change of length, during the test the automatic stop is not used, and curves like those on diagrams 1 and 2 are obtained. When ordinary structural material is tested, the stop is used, and a curve like that on diagram No. 3 is obtained; in this the elongation is drawn on a multiplied scale from 0 to the point marked "Stop;" beyond this it is drawn to natural scale. The very decided change of direction at the point marked "Stop" cannot be mistaken for anything else. As all of the instruments hereafter made will have a multiplication of ten times, this point of change of scale will be even more clearly defined than on the card shown. An investigation of the effect of stretch of the string or wire has demonstrated that it is negligible, and the divisions marked on diagram 2 will prove this. That it should be so will be clear when it is remembered that the drum revolves with a constant resistance, and that the string itself is always under constant tension, due to the small constant



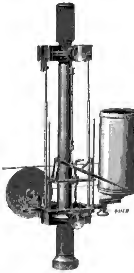


FIG. 3.

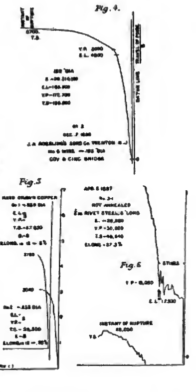

HENNING POCKET RECORDER.

* Iron and Steel Institute.

terweight tied to the string, C. It will be noted that at the instant of rupture the apparatus can separate into two independent parts, and that the knife edges permit a certain amount of slip; the combined effect of these two facts obviates any injury to the instrument at the instant of rupture, provided the accidental flying about of the gripping wedges is prevented by blocking them, which is always done by a careful person. Experience has shown that the instrument can be used rapidly without interfering to any degree with the work of the laboratory, and that the results are perfectly trustworthy.

[Continued from SUPPLEMENT, No. 1136, page 18156.]

PERPETUAL MOTION.—VI.*

FIG. 26 is an attempt to secure a perpetual motion by the application of electricity. It is the invention of a citizen of Kansas. In his communication inclosing the drawing, he says:

"You will observe friction (the old enemy) is an ally in this. If a magnet of a certain power will not move the electric plate, the power could be increased without perceptible loss of tension, by decreasing the resistance which the magnet and conductor offer."

In the engraving, A represents a frictional electrical machine; B, a crank; C, an electro magnet; D, wire conductors; F, a trunnion; G, an armature; E, a circuit closer; H, a pitman; I, an insulating substance; and J, spiral spring.

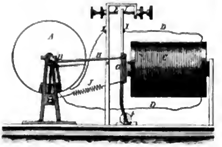

FIG. 26.

The device is expected to operate as follows:

The frictional electrical machine is started, which magnetizes the temporary magnet and draws the armature toward it. This breaks the circuit at the point, I, E, which demagnetizes the temporary magnet and allows the spring, J, to again close the circuit. By this means a continued motion is expected to be kept up.

To those not familiar with the science of molecular physics, this device may appear very plausible; a little reading, however, upon the subject of the correlation of forces will serve to show its utter fallacy.

Fig. 27 is the invention of Jean Clunet, of Lyons, France, patented in England, 1860, under the name of "A New and Improved Motive Power." It is thus described:

The invention relates to a new and improved motive power operating without noise and without expense. It consists in giving a rotary motion to a wheel, which is destined to transfer, by the ordinary means, the power obtained by the employment of any even, smooth blocks of stone, petrified mortar, iron, cast or wrought, or other heavy materials, in the form of cubes preferred, and of which the number and volume are governed by the amount of power desired, and causing them to descend in the ordinary atmospheric air, but to ascend in a liquid whose density is equal to their density, by which means their weight is annulled. For this purpose these blocks, when descending, are hung to hooks fixed to an endless chain turning upon the wheel receiving the motive power, which is of the shape of a hexagon, and placed on the top of a suitable framework, and upon another wheel of the shape of a square, which is placed at the bottom of said framework, and partially in a receptacle or tank of water, or any other liquid. When these blocks have arrived at the lower portion of their course, they detach themselves from the hooks on which hitherto they hung attached to the chain, which latter continues its ascending and rotary motion, and the said blocks descend and reascend within the tank, confined to their place and guided by an endless band and conducting wires stretched from supports for that purpose fixed on the top and bottom of the framework. They now, being thus guided, and following one upon another, find their way into another species of tank, placed vertically, likewise filled with a liquid similar to that in the first mentioned tank, and when arrived at the top of this second tank they tilt and slide along upon a horizontal shelf of rollers until they reach the hexagon-shaped wheel and the endless chain, when they recommence their descent. In order to prevent the liquid from running or descending from the second tank into the first, the blocks enter from one tank to the other between rollers and grooved pulleys pressed against the blocks by springs so as to shut off all way to the water. The detaching of the blocks from the endless chain takes place of itself, so to speak, from the position they find themselves in, in consequence of the rotary movement and of the turning over of the said chain upon the lower wheel in the shape of a square. The endless band receives a continuous descending and rising motion from the weight of the blocks, which give every motion that the apparatus possesses, and which motion would be perpetual, if, upon the axle of the hexagon-shaped wheel transmitting the force obtained to the machinery by means of a driving pulley keyed to one of its ends, there were not keyed to the other end a brake wheel with a hand crank, by means of which the movement may be stopped or modified. Instead of two receptacles, it would often be better to have but one, the rollers and grooved pulleys already alluded to being placed at the entrance of the single tank instead of the second, and acting in the same manner.

* Reprinted from the SCIENTIFIC AMERICAN, 1870-71.

The engraving is a side section, in elevation, of the whole apparatus.

A represents the blocks; B is the hexagon-shaped wheel; C is the endless chain, which remains attached to the said wheel by means of its pointed hooks, which successively enter similar recesses made in the circumference of the wheel, the other end of said hooks being square, serving to keep the blocks in their place while descending in conjunction with the conducting wires, D, placed two in front and two behind each block, and one at each side; E is the receptacle; F is the square wheel from which the chain, C, at the bottom of its course is detached to reascend round the wheel, B; G, rollers, of which there are four, made of India rubber or other elastic material, placed at the entrance of the receptacle, E; and H is the India rubber or other suitable angle pieces, also placed at the entrance, between which rollers, G, and angle pieces, H, pass with slight friction the said blocks, after being disengaged from the chain, C. These blocks, A, angle pieces, H, and rollers, G, being in close contact, form a permanent stoppage, so that the water cannot issue, and said blocks, when in the receptacle, are placed in the middle of the same, where they are kept in equilibrium by the water, and are pushed and moved forward by the blocks which descend after them. I is the endless band, resting on supports, J, fixed to the inside of the receptacle, supporting the blocks and moving with them. The blocks, when in the vertical part of the receptacle, are conducted by four wires, one on each of their four sides. K is a roller upon which tilt the blocks, guided by the endless band when on the top of the receptacle to leave the same; L, friction rollers, on which fall and roll the blocks after having tilted, in order to reach the hexagon wheel, B; M M are the two pulleys on each side of the hexagon-shaped wheel, for applying the brake and for transmitting the power obtained to other machinery. The equality in the density of the liquid and the blocks is obtained by hollowing the blocks so that they may easily rise to the top of the receptacle when therein. The desired result is obtained by the use of any other liquid, the volume of the blocks being proportionate to their density; also the weight of the blocks may be more or less than that of the liquid, but equality in weight is preferable.

No less a person than Sir William Congreve, M.P. and inventor of the famous Congreve rocket, figured in his time as a believer in, disputant upon and inventor of a perpetual motion. So sure was he that he had discovered the long-sought principle upon which self-moving machines could be constructed, that he patented his device, although we believe he never claimed to have succeeded in getting it to work. Nevertheless, he obstinately maintained that it would work, in spite of the mathematical demonstrations of the absurdity of his views made by several eminent mathematicians.

Fig. 28 shows this device. As will be seen, it is based on a principle hitherto not mentioned in this series of articles, viz., the power of capillary attraction.

Three horizontal rollers are fixed in a frame; an endless band of sponge runs round these rollers, and carries on the outside an endless chain of weights, surrounding the band of sponge, and attached to it, so that they must move together; every part of this band and chain being so accurately uniform in weight that the perpendicular side will, in all positions of the band and chain, be in equilibrium with the hypotenuse, on the principle of the inclined plane. Now, if the frame in which these rollers are fixed be placed in a cistern of water, having its lower part immersed therein, so that the water's edge cuts the upper part

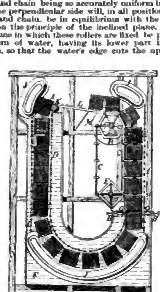

FIG. 27.

of the rollers, then, if the weight and quantity of the endless chain be duly proportioned to the thickness and breadth of the band of sponge, the band and chain will, on the water in the cistern being brought to the proper level, begin to move round the rollers in the direction of the arrow, by the force of capillary attraction, and will continue so to move.

On the perpendicular side of the triangle, the weights hanging perpendicularly alongside the band of sponge, the band is not compressed by them; and its pores being left open, the water, at the point where the band meets its surface, will rise to a certain height above its level, and thereby create a load, which load will not exist on the ascending side, because on this side the chain of weights compresses the band at the water's edge, and squeezes out any water that may have previously accumulated in it; so that the band rises in a dry state, the weight of the chain having been so proportioned to the breadth and thickness of the band as to be sufficient to produce this effect. The load, therefore, on the descending side, not being opposed by any similar load on the ascending side, and "the equilibrium of the other parts not being disturbed by the alternate expansion and compression of the sponge," the band will begin to move in the direction; and as it moves downward the accumulation of water will continue to rise, and thereby carry on a constant motion, provided the load be sufficient to overcome the friction on the rollers.

Now, to ascertain the quantity of this load in any particular machine, it must be stated that it is found by experiment that the water will rise in a fine sponge about an inch above its level; if, therefore, the band and sponge be one foot thick and six feet broad, the area of its horizontal section in contact with the water would be 864 square inches, and the weight of the accumulation of water raised by the capillary attraction being one inch rise upon 864 square inches, would be 30 lb., which, it is conceived, would be much more than equivalent to the friction of the rollers.

Now, the fallacy in this plausible argument is found in the words quoted. The equilibrium of the parts of the chain is disturbed at the moment the chain moves downward to compress the ascending file of sponges, and just enough disturbed to counterbalance the increase of weight on the perpendicular side. It is

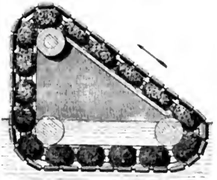

FIG. 28.

somewhat astonishing that a man of Sir William Congreve's ability should not have seen this at once, and still more astonishing that he should have disputed it when pointed out to him, which he did vehemently. Writing upon this subject, he says:

"For my own part, not being able to see any reason why the machine should not act, I confess that my faith is sufficiently strong to have induced me to take out a patent, and I am determined to use my best exertions to give mankind the benefit of this discovery, should it turn out, as I sincerely believe it will, a source of perpetual power without expense."

(To be continued.)

RAILWAY BUILDING IN THE NUBIAN DESERT.

A CORRESPONDENT of the London Times, writing from Wady Halfa on August 26, says that the railway between Wady Halfa and Abu Hamed, now in course of construction, is, from several points of view, one of the most interesting military lines in the world. For one thing, it crosses a portion of the Nubian desert which has apparently never before been trodden by the feet of man. In one place, however, it runs across what seems to have been the route taken a long time ago by a large body of men; for here, 60 miles from the nearest water, the engineers came across a mysterious collection of many hundreds of broken zeers, or earthen water coolers; they were two-handled, graceful amphoræ of a shape unknown in modern Egypt. This discovery naturally started a good deal of conjecture. Some remembered that Cambyses sent an army across this desert; then, to come down to more modern times, Ismail Pasha once dispatched a force of 2,000 men to Abu Hamed, which entirely disappeared in the desert and was never heard of again. Said Pasha, too, traveled in luxurious state to Abu Hamed in a carriage drawn by eight camels, with an army watering the desert in front of him to keep down the dust. The Cambyses theory as to the origin of these zeers is at present the most favored, as carrying us back to a respectable antiquity. There is yet another and a not unlikely explanation. There are numerous traces of ancient gold diggings in this desert. Do these broken vessels mark the spot where these diggers of old, of whom the Arabs have preserved no traditions, had one of their mining camps?

Describing a trip to the end of the line, the writer continues: When darkness fell we were well out in the desert, and, therefore, in a far more pleasant climate than that of the Nile bank, with its damp heat. Here the air was dry, pure and deliciously cool; it became even cold before dawn; one often needs three blankets to cover one at night at the summit of the line; here, too, we escaped for a time the ever irritating Egyptian flies. Even the air of midocean is not more sweet and invigorating than that of the wind swept, open desert, where, say the Arabs, the only diseases are hunger and thirst. So healthy, indeed, is it here that out of the 2,000 men working hard day after day in the sun on the railway construction there are rarely more than 12 on the sick list; and accidents account for the majority of these cases. It is noticed, by the way, that the men put on this work, receiving as they do regular and wholesome rations, rapidly improve in physique, increasing in size and weight to a remarkable extent. They all, both yellow Egyptians and coal-black Soudanese, appeared to be in the best of spirits. These people have a great capacity for railway construction, and seem to thoroughly enjoy their work.

Of the cheery, ever-grinning Soudanese, numbers were dervishes but a few months since fighting against us; and some were still wearing the jibbehs or Mahdist uniforms from which the colored patches had been torn off. One black ex-dervish worthy of mention is Sould, the Soudanese jester of the camp, who can al-

ways raise a roar of laughter in the working gangs, and is of distinct service, keeping up the men's spirits as he does by his clever mimicry and queer tricks. A bugler in Hicks Pasha's ill-fated army, he was captured by the dervishes and taken to the Mahdi's camp at Omdurman. There he discovered that he could make his life easier by playing the buffoon, and he became the jester of Wad el Bishara, the famous emir who commanded the dervish forces that were opposed to us last year. He used to be called up to amuse his master's friends by giving imitations of the British officers with whom he had been brought into contact. Recaptured by us last year at the battle of Hafir, he now, when not employed in rail laying, keeps the camp in a roar by his close imitations of his former master Bishara and other dervish notables.

Another correspondent, writing from Debbeh, says that all along the river posts civil tribunals have been established. There is a great demand among the natives for English stuffs and hardware, but at present the whole retail commerce is in the hands of Greeks. Last winter small quantities of gum and ostrich feathers were brought from Dar Fur, and it appears that a great amount of such goods is stored ready for sale as soon as the routes are open for trade.

THE FIRST-CLASS TORPEDO BOAT INJENIERO HYATT.

Messrs. Yarrow & Company, of Poplar, London, have sent us the following particulars of the first-class torpedo boat Injeniero Hyatt, which was one of six seagoing first-class torpedo boats lately built for the Chilean government by that firm. These vessels are 152 ft. 6 in. in length by 15 ft. 3 in. beam, and carry an armament consisting of two torpedo tubes and three quick-firing guns. They have a bunker capacity sufficient to hold 40 tons of coal and their radius of action is about 2,500 knots at a 10 knot speed. Two of these six vessels have been riveted up and tried successfully on the measured mile at the estuary of the Thames (full particulars of the trial annexed). The remaining four boats are being shipped in pieces with a view to being put together and riveted up in Chile. The Injeniero Hyatt left Plymouth on the 28th of April and arrived at Talcahuano on the 28th of June, having made in every respect a successful passage out, although during part of her run she encountered very bad weather. On arrival she went through an official trial with success, and on the examination of the boilers and the machinery everything was found in perfect order and quite satisfactory to the Chilean authorities.

These first-class torpedo boats were provided with two of Yarrow's patent straight tube water tube boilers, of about 1,000 horse power each, and weighing, including water and fittings, 9 tons each. It may here be remarked that lengthened experience has shown that this type of water tube boiler has an economy of at least 10 per cent. greater than the locomotive boilers of equal power which were formerly used in vessels of this class, and owing to the complete absence of leaky tubes through bad stoking, it has been found that less skill is required in the management of this type of water tube boiler than was necessary with locomotive or return tube boilers, because if, through bad stoking, cold air gain access into the furnace, it does not produce any injurious result.

THE FIRST-CLASS TORPEDO BOAT INJENIERO HYATT.

OFFICIAL TRIAL OF THE SEAGOING TORPEDO BOAT INJENIERO HYATT—FEBRUARY 15, 1897.

Draught of water, 4 ft. 1½ in. aft, 2 ft. 7⅜ in. forward; mean draught, 3 ft. 4½ in. Load on trial, 27 tons. Propeller, 7 ft. 6 in. diameter.

During the three hours' full speed trial in the estuary of the Thames the following runs were made over the measured sea mile on the Maplins:

Number.	[illegible]	First Receiver.	Second Receiver.	Vacuum.	Air Pressure.	Revolutions per Minute.	Time.	Speed in Knots.	First Mean in Knots.	Second Mean in Knots.		Slip.
1	175 lb.	77 lb.	12 lb.	24 in.	1¼ in.	344	2' 31"	23·841	25·983	26·187		48
2	180 "	77 "	12 "	24 "	1¾ "	345	2' 8"	28·125	26·391			
3	185 "	80 "	14 "	24 "	1½ "	350	2' 26"	24·657				
4	190 "	84 "	14½ "	24 "	1 "	363	2' 5"	28·800	27·257	27·232	27·219	38
5	190 "	84 "	14½ "	24 "	1¼ "	360	2' 20"	25·714	27·207	27·207		
6	190 "	84 "	14½ "	24 "	1¾ "	364	2' 5⅛"	28·700	27·207			
7	200 "	86 "	15 "	24 "	1½ "	363	2' 20"	25·714				

Mean revolutions per minute during three hours, 353·4, equal to 26·8 average speed in knots.

After the three hours' speed trial, circles were turned to starboard and to port in a space equal to about three times the length of the vessel. No trouble was experienced with either engines or boilers.

STEAM POWER IN THE FISHING BUSINESS IN EUROPE.

By Charles Theodore Mason.

The use of steam in the fishing business, says Mr. Georges Roche, in an exhaustive article on the subject in a Paris magazine, permits the regulating of the work at sea, while, at the same time, it assures the product of this work being delivered on land in good condition and in the shortest space of time possible. It also gives more security in the navigation, often difficult, of the fishing boats, and lessens the fatigue of the crew, so far as the handling of the tackle is concerned.

Steam is employed on board these boats either for the propulsion of the boats themselves and the handling of the tackle, the handling of the tackle alone, or for taking the product of the work to land. Steam fishing boats are utilized for the capture of fish with deep sea lines, with drag nets, or, as in the case of herrings and mackerels, with floating nets. Compactly built, more with a view to remaining at sea in all weathers than to furnishing them with a speed that they hardly need, these boats generally remain away from land for several days, in some cases even weeks, fishing in company and relieving each other in the task of taking the fish they have all caught to land. Many small tugs or coasters, and even yachts have been transformed into fishing boats, but at present steamboats are expressly built for the purpose.

The characteristics of a good type of steam trawler were given, in 1889, in the Revue Technique de l'Exposition Internationale. The boats referred to were built by an amateur of Dieppe and were intended only for work in the English Channel, but boats of this class must vary in form and construction according to the marine regions in which they are called to fish. The characteristics are as follows: Length between perpendiculars, 70 ft.; breadth, 18 ft.; depth, 8 ft.; draught, 6 ft., and the horse power 100. The speed of such boats was set down at nine knots an hour.

The characteristics of a Scotch steam trawler were given in a Bulletin of the Society for the Technical and Professional Teaching of Maritime Fishing, by Mr. P. Dunbar. The length of this boat was 120 ft., its breadth, 33 ft., its draught, 11 ft.; and the indicated power of its machinery, 500 horse power. The common type of these fishing boats doing a similar work is, however, only 100 ft. in length, with an indicated horse power of 300. The net cost of a steam trawler is from $16,000 to $19,000, but smaller ones may be had for $13,000. A sailing trawler furnished with a steam apparatus for hauling in the seine can be bought at Boulogne for about $5,000, but the herring and mackerel smacks, being of a greater tonnage, cost from $5,500 to $7,500.

In France, the ports equipped with steam fishing boats are fairly numerous. Of these, Boulogne supplies 3 large trawlers and 22 smaller ones; Dieppe, 73 of the first and 11 of the latter. Boulogne has also 200 sailing boats equipped with steam haulers, and Fécamp some 40 or more. Some of these last practice trawling in the Channel and in the North Sea, but the majority are engaged in mackerel catching in the Irish Sea, and, during the season for it, herring catching in the North Sea. Some years ago, fishing with steam was started at Trouville, but failed dismally, not, however, on account of any insufficiency in the production of the finny tribe. Between Fécamp and Arcachon there is at present only one boat equipped with steam haulers. Arcachon supplies 8 such boats (five of which belong to the Société des Pêcheries de l'Océan), while S. Jean de Luz supplies 3.

On the coasts of Great Britain there are more than 300 steamboats built of iron, 32 of steel, and 60 of wood, engaged in trawling in the North Sea alone. Some of these are provided with vivaries for carrying the fish alive to land. This large number is still increasing, but on the east coast only, for the boats of this class hardly amount to more than 20 on the west coast. In addition to these steamboats, the English fisheries employ a considerable number of sailing vessels equipped with steam apparatuses for taking in the seine, these vessels being kept in communication with the neighboring ports by means of steamboats, plying constantly to and fro from the fleet. These boats work in company, and in the vicinity of the North Sea banks. As soon as the fish are captured they are put, with small lumps of ice, in boxes specially constructed for the purpose, and in such a manner as to be easily handled. The steamboats, above alluded to, collect these boxes, after delivering whatever provisions, etc., they may have brought with them for the fleet. . . . The boats that work in company engage to remain at sea for two, three, and four months at a time. At Yarmouth, 700 of these sailing craft are employed, summer and winter, in this kind of industry; at Hull, 300 sailing vessels fish in company, and at Grimsby a like number are employed. It was Messrs. Hewett & Company, of London, who, in equipping a large fleet of trawlers, organized the first system of rapid transportation of fish to the various markets along the coast. The boats were then large sailing vessels; but, in 1864, the firm decided to equip steamboats for the purpose. It was not until 1880 that the adoption of these steamboats took place at Hull. The chief ports of Great Britain equipped with these steam craft are Aberdeen, Granton, Leith, North Shields, Sunderland, Hull and Grimsby.

In Germany, in 1884, a fish merchant of Geestemunde on the embrasure of the Weser, equipped the first steamboats for deep sea fishing. In 1889, 25 of these boats were employed on the west banks of the North Sea and in the neighborhood of Norway. To-day this number has increased to 100, working between Hamburg, Geestemunde, Bremen, Emsden, and Lubeck. Some of these are occupied in catching herrings with nets, others with lines, and the rest with trawling nets. In Germany deep sea fishing is an object of solicitude on the part of the government as well as of private societies. Hence it is that in the comparatively short space of 15 years a very important industry has been built up by Germany in the North Sea. In some of the markets where the French have been in the habit of selling a large quantity of salted fish the German fisheries have established a connection that threatens to drive the former out of the business, so far, at least, as these markets are concerned. Holland and Scotland have also begun to feel the effects of German competition.

The Emperor has founded a prize intended as a recompense to the designer and builder of the best model steam fishing boat, and a second prize is to be given to the person who designs the best sailing boat provided with mechanical hauliers. Both designs must be studied with a view to economy and simplicity.

In Holland the number of steamboats engaged in deep sea fishing is considerable, and mention must not be forgotten of the ostreiculture of East Escaut, which employs steamboats for the exploitation of the territory conceded it. Moreover, in the lower part of the Rhine and the Meuse, the seines are worked by means of steam apparatus, with the view to capturing the salmon which abound in these rivers, and of which some 60,000 are annually taken.

In Spain of late years a flourishing enterprise in the fishing industry has been established. At Vigo some 40 steamboats are engaged on the rocky banks which skirt the coast in this direction; while some 20 of a larger build, and worked by steam, practice trawling in the Bay of Biscay, coming sometimes as far north as the mouth of the Gironde.

To be successfully practiced, steam fishing requires a considerable outlay of capital. Hence, in England it is practiced only by large companies; while in France, Spain and Germany amateurs or private fishermen mainly interest themselves in it. Nevertheless, in certain ports, as at Groix, in France, the sailing trawlers are owned by a company of fishermen. Not long since, in the west of France, where steam fishing has only been known for some twenty years, a trawler from the Gulf of Gascogne returned, after an absence of twelve days, with a cargo that was sold for 4,000 francs ($800). A Grimsby fishing boat has also brought back to land, as the result of fourteen days' fishing, a cargo worth 545 pounds sterling ($2,725), while, in 1894, a steam trawler from Geestemunde made a haul, during Easter week, that was sold for 14,000 francs ($2,625).

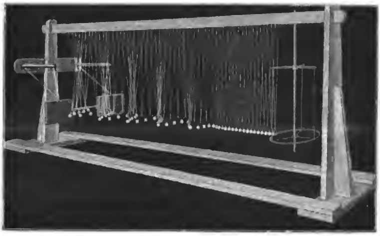
In France boats provided with vivaries are only used for the transportation of lobsters and crayfish. In England, Holland, Denmark, Norway and Germany these boats, however, are in constant use, much attention being paid in these countries to this means of preserving the fish alive. Fish thus taken alive to the markets enjoy a much greater favor in the eyes of the public than fish preserved in ice. These vivaries are either a part of the boat itself or else are large movable basins attached to its side. In either case, the water is renewed by the progress of the boat, the liquid being communicated to the deck by means of a kind of well in which the action of the swell is felt. A large number of the French fisheries still continue to make use of ice only as a means of taking the fish alive overland. The Société des Pêcheries de l'Océan, for instance, has organized the work in such a manner that the products of the trawling fleet (some five in number) are taken ashore every day by one of the boats, ice being employed only in transit by rail inland.

In the interests of the preservation of the product which they collect, it is to the advantage of the fisheries to employ steamboats as well as to equip the sailing boats with mechanical haulers. It is not enough that the fish be kept for as short a time as possible in ice; it is also necessary that they remain for as brief a period of time as possible under the water after they have

been captured. Moreover, when the tackle is drawn on board by hand, the fatigue occasioned by the operation is such that the work can hardly be performed more than a limited number of times a day. Hence a mechanical hauler would render the greatest possible service to every trawler that has not yet adopted it, while the resultant gain in money would be considerable.

A HERTZ WAVE MODEL.*

IN the spring of the present year I showed, at a meeting of the Physical Society, of London, a wave motion model which I designed to illustrate mechanically the propagation of a transverse wave. As the exhibition of this model on that occasion, and subsequently at the Royal Society and Royal Institution, has elicited a number of inquiries about the apparatus, it is thought that the following brief account of it may be of some interest to lecturers on physics, particularly at a time when the propagation of electric waves through space is occupying much attention. The apparatus, which is depicted in the accompanying cut, is mounted on a strong wooden frame about two meters long. At one end (the further in the cut) is the "oscillator," a heavy mass of brass hung by two strong V cords from arms which project parallel to the longer dimension of the frame. This mass, which, for the sake of analogy, is quite unnecessarily shaped to imitate an orthodox electric oscillator, can therefore be set swinging in a transverse direction by a suitable impulse given by hand. At the other end of the frame (the nearer in the cut) is the "resonator," a circle of brass wire hung by a tri-filar suspension. Oscillator and resonator must be adjusted by shortening or lengthening the cords so as to have identical periods of oscillation. The real problem in the construction of the apparatus was to find a mechanical means of transmitting the energy of the oscillator in visible waves to the resonator. The means finally adopted was a series of inter-connected pendulums on a plan somewhat similar to one suggested† in 1877 by Prof. Osborne Reynolds. Instead of using springs, however, the requisite inter-connection is obtained by simply suspending the leaden bullets which act as pendulum bobs by V suspensions which overlap, and which, as shown in the cut, are tied together at a point about four centimeters above each of the balls. No ball can be laterally displaced without tending to drag its neighbor also; so that a shearing stress is transmitted along the line of balls. As Reynolds showed twenty years ago, the velocity of propagation of the wave front differs from that of the group of waves, owing to the continual dying away of the amplitude of the advancing waves. This effect, due to the inertia of the medium, is of course equivalent to the presence of dispersion in the medium, waves of different frequencies being propagated with slightly different velocities. So far, therefore, as Prof. Fitzgerald remarked when the model was exhibited, it illustrates the propagation of the wave in a refracting medium rather than in the ether of space. The waves in the model travel quite slowly; and there is a fascination in watching their progress along the row of balls, until they arrive at the resonator and set it into responsive vibration. There is, of course, no attempt made here to represent the magnetic part of the electromagnetic wave at right angles to the electrostatic part; the mechanical displacements in the model corresponding to the electrostatic displacements of the Hertzian wave. A row of inter-connected pendulums such as this affords a means of illustrating many points in physics. For many purposes the elaborate system of suspension by strings may be replaced by a continuous fabric. Thus, for example, a piece of netting, hung on hooks from a horizontal rail, and ending below in a short fringe, with leaden beads on the fringe tips, will also serve to illustrate the propagation of a transverse wave. The structure adopted absolutely refuses to transmit longitudinal disturbances; there being no compressional elasticity between the balls to propagate a longitudinal wave.



MECHANICAL MODEL ILLUSTRATING PROPAGATION OF A HERTZ WAVE.

DIRECT PHOTO-LITHOGRAPHY ON STONE.

IT is rarely attempted to print direct on to the stone, although all the earliest experimenters in the process directed their efforts to this end. It is admitted that there would be considerable gain in a direct print, the loss of sharpness and delicacy by transfer even under the best conditions being sufficiently obvious, but most workers who attempt direct work appear to find the difficulties too great, and fall back on the easier method of paper transfers. Yet it is very probable that, like many other old processes of great practical merit, direct photo-lithography fell into desuetude because those who tried to work it lacked the necessary patience to master the details and conquer the difficulties which always crop up in working a new process.

Recently the writer was led to try a method of direct printing on stone, and found it far from being so difficult as it had been represented, and after two or three attempts a really good print was obtained, possessing a sharpness which could not be got with any transfer method. Afterward the process became comparatively easy as practice was gained. There are many lithographic firms which would be only too glad to find a man who can print direct on stone, and a study of this process may be recommended to young photographers who do not see any very rosy prospect in the present position of portrait photography.

The process we used was based on the published method of Poitevin, but modified as we shall describe. It will be best first to quote the original description, or rather a translated version of it.

Poitevin says: "A hard and close grained Bavarian lithographic stone is to be preferred. The surface being smoothed and finely grained, I wet it, and having removed the excess of water, I apply with a brush the bichromate mixture, composed of an egg beaten up, passed through a piece of linen, and mixed with an equal quantity of saturated solution of bichromate of ammonia. With a sponge I clean the edges of the stone, and with a linen dabber I remove the excess of solution by dabbing, but without rubbing, and with a drier cloth I remove the remainder of the liquid in the same way until the stone no longer moistens the finger when touched. By working thus, only a very small quantity of the bichromated mixture penetrates into the stone and forms there a very regular inner layer without covering its surface. Without waiting for the complete drying of this layer, I apply to it the photographic cliché, if of paper, by keeping it in place by means of a glass plate fastened down by means of pellets of soft modelling wax. I have also used a special pressure frame to hold the stone and negative, but the way I have described answers ordinarily. If the negative is on glass, I fix it with wax. I expose the prepared stone either to direct sunlight, falling perpendicularly on its surface, or to diffused, laying the stone horizontally. The time of exposure is very variable in summer (from ten to twelve minutes in the sun), and in winter from an hour and a half to two hours; in the shade the exposure will be from four to five times longer. In any case the latitude is great, and it is better to expose too much than too little, because over exposure can be corrected in the inking of the stone and by the etching and proving, while too little exposure prevents the greasy ink from adhering to the half tones, and that cannot be remedied.

"After exposure to light the stone is taken into the inking room, and there left for some time to take the temperature of the surrounding air, whether it may have been too much warmed or chilled, according to the temperature of the time of year.

"The stone is moistened with a sponge dipped in a solution containing one-third of glycerine to two-thirds of water, and having removed the excess of liquid, I pass a roller charged with transfer ink and varnish all over the stone. The image then appears gradually, the parts which have received the action of light retaining the fatty ink, while the others, corresponding to the whites of the drawing or opaque parts of the negatives, repel it. The stone is damped lightly with ordinary water, and the inking is continued until the drawing has attained the desired strength. If the stone should have been over-inked, the whole is removed with turpentine, the stone is wiped and damped, and the inking-in is done again more carefully with the roller less charged with ink.

"The stone is then left at rest for about twelve hours, in order that the fatty ink may penetrate it and be fixed more completely. It is then gummed. After an hour it is washed, the gum removed, and the stone is then rolled in with ordinary printing ink, etched and proved by pulling a few proofs, just as in the case of an ordinary chalk drawing on stone.

"If the exposure to light has been insufficient, the fatty ink will take with difficulty and the proof will be wanting in half tone; on the contrary, if over-exposed, the image will be heavy and blocked up, but in the majority of cases a good proof is obtained, because there is a great latitude in the exposure if the lithographer is skillful in working up the image. In any case it will always be better to expose a fresh tone rather than to hand over a bad impression to the printer."

It must be noticed that Poitevin is here describing a method of half-tone transfer, and for this reason he speaks of the surface of the stone being finely grained. For a line engraving, or a print from a half-tone negative made with the ruled screen, the smoother the stone is the better, and therefore the polish should be the highest it is possible to obtain, and care should be taken that the stone has been ground quite flat. Any hollows will give trouble. The quality of the stone is of importance, and it should be for preference that rather scarce kind, the gray stone. The yellow stones can be used, but not so easily. The surface of the stone should, of course, be scrupulously clean. Any finger marks would leave a greasy stain which would attract the ink. In coating the stone as described, there would be a difficulty in getting an even film, and the writer prefers to warm the stone in front of a good fire until all the moisture is driven away from the surface of the stone, which then becomes quite warm. The sensitizing solution, exactly the same as used for zinc, is flowed on and spread with a glass rod if it does not flow well.

It is best not to allow any solution to go over the edge of the stone, as it has a tendency to creep back, bringing dust and grit with it, and setting in dirty ridges. The warmth in the stone quickly dries the film, and when quite dry it is ready for exposure. Small stones can be screwed up in a specially made deep printing frame with plate glass front. There is not so much risk of breaking the negative as might be supposed. Poitevin's method of attaching the negative to the stone with pellets of wax is a convenient way, provided the negative glass is flat and the exposure made inside a deep box with blackened sides, so that the light falls perpendicularly.

A better plan is to use stripped film negatives, squeezing them into contact with the stone after having given the latter a light coating of castor oil or vaseline applied on top of the sensitive coating by means of a gelatine roller. The film will then adhere very firmly to the surface; the oil or grease does no harm, as it mingles with the ink when the rolling up comes. The printing does not take so long as Poitevin says. It is, in fact, pretty much the same as for zinc—about three minutes in good sunlight and from fifteen to thirty minutes in diffused light or shade. The temperature of the stone while being inked is quite as important as Poitevin points out. The ink used should be "stone to stone retransfer," applied with a leather roller as stiff as it can be worked. It must be well distributed, and the most delicate coating applied to the stone. Anything like blackness must be avoided; it will simply be an olive gray tint. Then the water from tap or hose pipe is allowed to run over the stone for some minutes, and an indistinct image will be seen. With cotton wool on a soft sponge the surface is gently rubbed until the ink is loosened and comes away. Eventually, if the exposure and other conditions have been correct, a beautifully sharp and black print on the stone will be secured. This is dusted over with very fine resin, and etched with acidulated water, about vinegar strength, after which it is gummed and rolled up in the usual way familiar to all lithographers. The result should be a print very much superior to transferred work, and it will retain its sharpness even during a very long run on the machine. The only drawback is the weight of large stones and the difficulty of handling them in the dark room, but the process has a wide application with small subjects, for which the stones are comparatively light.—Photography.

ON PRACTICALLY AVAILABLE PROCESSES FOR SOLDERING ALUMINUM IN THE LABORATORY.*

IT seems that, ever since the metal aluminum has been used in construction, difficulties have arisen in soldering it. Further, from contemporary literature it appears probable that some perfectly satisfactory methods of getting over the difficulty are known, but not published in sufficient detail to be available.

Hence it seems well to put on record any advance toward the solution of this somewhat troublesome problem. In the first place, my experience is that it is not easy to solder aluminum simply by using an alloy of definite composition without a flux. Also that the only other process which does not require special apparatus, that based upon the use of silver chloride, is very troublesome indeed unless the local fusion of the aluminum be immaterial. I find, however, that cadmium iodide is distinctly more satisfactory. If it be fused on an aluminum plate, decomposition of the salt occurs long before the melting point of the aluminum is reached. The result is generally the violent evolution of iodine vapor and formation of an alloy of cadmium and aluminum on the surface of the metal.

The decomposition of the cadmium iodide is, however, too rapid to be convenient, and the pulverulent white residue is in the way. It is, therefore, of advantage to add some other body which, if possible, will obviate these defects. I find that zinc chloride answers fairly well. Thus I mix concentrated zinc chloride solution with a little ammonium chloride, evaporate in a round porcelain dish, and ignite at a low red heat till a part of the ammonium chloride is volatilized. The fused chlorides are now mixed with cadmium iodide. The proportions of zinc chloride and cadmium iodide are best adjusted experimentally.

The final result, when the salts are completely fused together, is a flux which readily enables tin (or other soldering alloy) to unite perfectly with aluminum. The melted flux can be taken up in a pipette with India rubber teat, and dropped on to the surface of the metal to be soldered. Some powdered metallic tin is also sprinkled on the surface. The aluminum is then heated over the Bunsen flame till the flux just melts; it can then be quickly spread where it is wanted with a piece of copper wire or thin glass rod. As the temperature is farther raised the flux decomposes, and the tin readily alloys itself with the surface of the aluminum; while the flux is decomposing, the tin can be spread in a continuous layer by means of the little glass rod or wire.

Instead of cadmium iodide, fused lead chloride may be used in a similar manner.

I should like to substitute some of the less volatile alkyl-ammonium chlorides for the ammonium chloride, but have not had opportunity.

ENGINEERING NOTES.

Seagoing barges of large capacity are coming into use at Hamburg since the opening of the Baltic-North Sea Canal.

The system of locomotion by machinery is now superseding that of traction by horses, not only in tramway service, but for omnibuses. The Berlin omnibus company is introducing for trial omnibuses propelled by electricity from a secondary battery. The charge is renewed at the two terminal stations.—Uhland's Wochenschrift.

There are in Sweden at the present time 146 furnaces in blast. The production of pig iron, the bulk of which is smelted with charcoal, amounts to 462,930 tons per annum, which represents a daily production of 12·8 tons per furnace. According to The Iron and Coal Trades Review, in 1895 there were in the country 30 Bessemer converters, 33 open hearth furnaces, and 5 crucible steel furnaces.

Statistics show that the number of German and English vessels passing through the Suez Canal is approximately in the same proportion as the size of the corresponding fleets, namely, 1:7. The canal was opened in 1869; in 1870, 486 ships passed through it, in 1896 this number had increased to 3,409. The corresponding increase in tonnage is, however, much greater, the first year's total being 655,000, and that for 1896 being some twenty times as much, namely, 12,000,000. The greatest ships that pass through the canal are the German mail steamers of the East Asiatic Line.—Uhland's Wochenschrift.

The use of acetylene for driving engines is, according to Revue Industrielle, entirely possible, as shown by a series of experiments conducted at Compiegne by Cuinat. It was shown that acetylene develops fully three times the energy of the usual illuminating gas and that the only changes needed to transform an ordinary gas engine into an acetylene engine was a reduction in size of the intake valves. The best mixture was found to be 10 of air to 1 of gas. With these proportions it was found that engines ranging from 8 to 16 h. p. cost about 6 cents per h. p. hour, at the present rate of calcium carbide.

The first cargo of molasses to be sent across the Atlantic Ocean in bulk from this country, it is stated, will be that taken out from Philadelphia by the British tank steamer Petriana. She has been chartered by parties in New York to carry about 600,000 gallons of sirup molasses, which have been purchased from the sugar trust. The port at which the cargo will be landed is London. A great deal of money can be saved, it is said, by shipping it in this way. The cost of cooperage, etc., will be saved, as it will be necessary only to pump the liquid into the vessel's tanks.—Philadelphia Ledger, September 18.

The pipe mills of the Reading Iron Company, probably the largest concern in the United States making black and galvanized iron pipes, have commenced running day and night. One million pounds of pipe, ranging in size from one-eighth of an inch to twelve inches in diameter, are turned out each twenty-four hours. Recently there has been a great influx of foreign orders, and the mills will be kept busy for some time to come making pipe for export to Australia, Africa, England, various countries in the European Continent, Mexico and India. Ten carloads of pipe were consigned to Singapore recently and much more is to follow.

At Toulon the French battleships Brennus, Neptune and Marceau have been engaged in target practice against the hull of the old dispatch boat Pétrel, which was towed with a couple of sails hoisted by the Travailleur, while the Linois, in a position perpendicular to the line of fire, observed the results. She had on board several officers of the squadron as a committee to report, says The Army and Navy Journal. The Brennus discharged twelve rounds from her 13·3 inch guns and eighty from the 6·2 inch guns, the Neptune 100 rounds from her 12·5 inch gun, and the Marceau six rounds from the large guns and 160 from the 5·5 inch quick firers. Thus in all, 298 rounds were discharged at the vessel and at certain targets which were in tow. Very often the shells fell short, but there were many hits, and some of the projectiles went through the boat without causing any serious damage. Others, however, spread destruction where they fell, and the above-water portions on the port side were almost demolished, while there were some hits below the water line. It was observed, however, that few shells struck the Pétrel between wind and water, but this was accounted for by the great range. The dispatch vessel did not sink, notwithstanding the battering that was given her, but was towed back to Toulon for examination and to be fitted for some further trials toward the end of the month.

We are quite accustomed to see iron or steel arched bridges hinged at the crown and abutments, but to treat a masonry arch in this manner would at first sight appear to be rather venturesome. In Germany, however, several bridges were built some few years ago on this principle, one of them having an effective span of 150 ft., and the result has been quite successful, both from a constructional and from an economical point of view. A complete description of this method of construction was contributed by Mons. G. La Riviere to the Annales des Ponts et Chaussées soon after the bridges were built, and is well worthy of careful perusal. The author draws attention to several curious features in the design of these bridges, but by far the most remarkable is the introduction of the three joints in the masonry ring. These joints, which really act as hinges, are placed one at the crown and one at each abutment, and prevent, of course, the line of pressure deviating very much from the center line of the arch ring, thereby removing all ambiguity as to the actual stresses. The rise of the arches in some cases is not more than 1/10 the span, and no masonry backing is employed, the roadway being supported from the arch by means of thin spandrel or cross walls. The hinged joints are made by inserting sheet lead about 1/8 in. thick, extending over only the middle third of the arch stone. At first it was thought that this joint should be made by means of bearing plates and pins, much in the same way as would be done in a steel arch, but this arrangement was subsequently abandoned in favor of the sheet lead.

ELECTRICAL NOTES.

The last horse car line has lately been abolished in Stuttgart (Germany) and electric cars have been substituted. With this all street cars in Stuttgart are now electrically propelled.—Electrotechnische Rundschau.

Suspended railways offer several advantages over the ordinary style of cars. They are less noisy, occupy less space, and have a very gentle motion, which is agreeable to the passengers. Such a line is to be constructed from Dresden (Germany) to the surrounding country; cars are to run every two or three minutes, at a rate of 25 to 30 miles per hour, or, if the stoppages are taken into account, at about 14 to 18 miles per hour.—Electrotechnische Rundschau.

The effect of moisture and heat on electricity insulators is dealt with in a paper read at the recent meeting of electricians at Eliot. In the discussion that followed the reading, Prof. Perrine states that more than 4 per cent. of the total weight of a No. 18 copper cable, covered with paper 0·128 in. thick, can be driven off by evaporating the moisture it contains. Even in dry climates, like that of California, 15 per cent. of the weight of such a paper sheathing is due to moisture. Some specimens of wood were shown which, after being thoroughly dried, had, in three days, added 15 per cent. to their weight by absorbing moisture from the air. Cellulose compounds are unstable at ordinary temperatures, but at 100° they slowly carbonize and fast deteriorate in insulating value.

In the Journal of the Society of Chemical Industry, M. Andreoli remarks that, though theoretically one should be able to produce a kilo of ozone per electric horse power, in practice only ten or twelve grammes are obtained. By improvements, however, in apparatus for the production of ozone, M. Andreoli is now able, he contends, to increase the amount to thirty and in some cases even fifty grammes per horse power, making the cost about 75 cents a kilo. This, if a practical thing applicable on a large scale, is important. Based on these results, experiments are to be made by him in various directions, to ascertain the value of the process in commercial affairs, such as the purification of drinking water, the cleansing of beer casks, preparing wood for instruments and furniture, bleaching of starch and dextrin, oxidation of drying oils, purification of wine and brandy, etc.

According to L'Eclairage Electrique, the Sussmann electric miner's lamp was recently tried in Belgium, and gave very satisfactory results. The accumulator used is one containing a solid electrolyte. An incandescent lamp is fixed above the accumulator, and is inclosed in a special case; the ebonite box, measuring 5 in. by 3½ in. by 2¾ in., is divided into two compartments, each of which holds two negative plates and one positive, which are separated by rubber bands. These plates are pasted; the two cells are connected in series, and give an electromotive force of about 4 volts. The lamp, complete and ready for use, is somewhat heavier than the ordinary miners' lamp, its weight being 4·3 lb., and its capacity 12 to 26 hours, burning under normal conditions, the light given being from two and a half to five times that of an ordinary miners' lamp. The power required for charging was found to be about 3¼ horse power per 100 lamps.

About the surest beacon of prosperity is a sawmill, and when we find one like this at Port Blakely, Wash., than which there is but one other larger in the world and none bigger in the United States, we are inclined to stop to regard it. The whole plant is lighted by electricity, and at present the mill is running night and day, with three shifts of men for the twenty-four hours. Electricity is also used for motive power in the planing and finishing departments and in the blacksmith and pattern shops. Their lathes, planes, moulding, and pattern workings are so complete that they are enabled to supply any portion of disabled machinery at short notice, and last year furnished fifty tons of castings for their own repairs. The company also owns and runs a gristmill for a supply of the logging camps, a hotel for visitors, a hall for public meetings and church purposes, and a town of some 200 houses. Their general store carries a stock complete in every line, from a package of pins to the largest hawsers and cables.

The Antwerp correspondent of The Liverpool Journal of Commerce says that for some time there has been a desire expressed that the electric light should be used for loading and unloading vessels at night, owing to the many serious fires which have taken place at frequent intervals from the upsetting of the old fashioned oil lamps, which have been used since time immemorial. The first experiments with this object in view took place at dock No. 5, five arc lamps being used to light up the quay. When work is not going on, the lamps are hung on arms connected with the cranes; but when a vessel is being worked after dark, the lamps are carried about and hung at points where they can throw the most light into the hold, thus enabling the men to work as in broad daylight, and the custom house officials and tally men take their notes with perfect ease. The danger of fire is reduced to a minimum, and thieving will be less. It is hoped that after this experiment, which has proved so successful, the entire quay system will be furnished with these portable arc lamps.

A very successful and beautiful trial demonstration of the lighting by electricity of the whirlpool rapids of Niagara Falls was given recently, says The Electrical Review, during the conventions in that city and greatly pleased every observer. Special parties of ladies and gentlemen took the Gorge route cars, accompanied by a flat construction car carrying the searchlights and appliances. Current was taken from the trolley wire, six searchlights being supplied, and magnificent color effects were produced on the surging waters by means of the usual color screens. Mr. Luther Stieringer originated the scheme, and through the liberal assistance given by Capt. J. M. Brinker, president of the Gorge road, and Superintendent J. K. Brooks the work was carried to a most successful issue. The apparatus was furnished for the occasion through the courtesy of the General Electric Company. Further private trials are in progress to determine the proper arrangement and quantity of light required to illuminate these rapids in the most effective manner. Numerous requests for the repetition of this novel lighting during the American Street Railway convention in October have been made, and, if possible, will be complied with.

MISCELLANEOUS NOTES.

To distinguish benzine from benzole, add some potassium iodide crystals. Benzole is colored red by this salt, while benzine remains unchanged. If benzole is shaken up with a little alcohol, it turns milky, while benzine does not.—La Science en Famille.

Of two lots of gold from the Klondike received at the New York Assay Office, says the Engineering and Mining Journal, one assayed 0·749 per cent. gold and 0·246 per cent. silver, which made the value $15.48 an ounce, while the other assayed 0·820¼ gold and 0·174 silver, making the value $16.95 an ounce.

L. Davy, in Comptes Rendus, cxxv, No. 8, says that all authors who have studied the ancient working of tin in the west of Europe admit that it was far anterior to the occupation of the country by the Romans, and think that the mines of Abbaretz-Nozay were abandoned by the Gauls about the date of the Roman invasion.

An arrangement by which more than one note may be obtained from a single bell is being made by Mr. Slnaber, of Reading, according to a patent granted to him. The device by which he gains this end consists merely of a number of dents, which divide the whole bell into several sections of different sizes. Each section, when struck, gives a note corresponding to its size.—Wiener Gewerbe Zeitung.

Of all postal service, that in East India is the most difficult. There are 4,000 packages monthly which do not reach their destination on account of not bearing any address. The multitude of Hindoo dialects is another great difficulty the postal officials have to contend with, and the postmen are exposed to considerable danger from wild beasts.—Uhland's Wochenschrift.

It is stated in Machinery that acetylene is now in use in several of the Paris omnibuses. The generator weighs about 20 lb., and is carried under the front steps. Each load of carbide is about 0·72 lb., and produces about 3 cubic feet of gas, which is enough for 6¼ hours, with a light of 16 candles. The pressure is regulated so as not to exceed 4 in. of water. The cost is less than that of petroleum. Electrical accumulators to do the same work weighed nearly 3 cwt., and did mischief, so that they were glad to give them up.

Herr Nebendahl, of Wandsbeck, Germany, has invented a device for the automatic lighting and extinguishing of street lamps. The working of this apparatus is based on the difference of the pressure at which the gas is supplied during the day and at night, and is so delicate that it is sufficient to have that difference equal to 7 millimeters of mercury. The device consists of a cup containing glycerine, into which dips an inverted bell. This bell is connected to a lever, and by a pipe to the gas conduit. When the pressure of the gas is low the bell is also at a low stand, and the lever admits the gas only to a small lighting flame. When the pressure is raised the bell rises, and the lever opens a cock to the main flame.—Uhland's Wochenschrift.

The management of the French State Railways has obtained the permission of the Minister of Railways for the construction and reconstruction of a number of railway passenger carriages, in which all the parts formerly manufactured of brass, copper and iron, with the exception of axles, wheels, bearings, and springs, brake beams and couplings, shall be constructed of aluminum. The weight of a carriage with aluminum fittings is one and a half tons less than that of an old style carriage. As an ordinary train in France consists of twenty coaches, the weight of the train could be reduced by thirty tons, which would mean a considerable saving in working expenses. It remains to be seen whether aluminum will prove to be as durable as the other metals for the purpose.

E. W. Parker, of the United States Geological Survey, has prepared a report showing in fifteen States the increasing use of coal mining machines from 1891 to 1896. In the former year the amount of coal mined by machines was 2,739,743 tons. This was 3·3 per cent. of the total amount of coal mined that year. Ohio mined 1,654,081 tons by machinery, or over 60 per cent. of the total machine mined coal. In 1896 these fifteen States mined by machinery 12,553,522 tons, which is 13 per cent. of the aggregate output of those States for the year. Ohio increased its machine mined coal from 1,654,081 to 8,308,349 tons, while Pennsylvania increased from 213,492 to 6,092,644 tons. The total output of the fifteen States increased 16 per cent. from 1891 to 1896. The machine mined coal increased 400 per cent. There is no reason to believe that the machines will not be still more widely adopted in the future, since their economy has been demonstrated. While the operation of the machines is easily acquired by a miner, their more general use will tend to increase the average intelligence and skill of the miner.

According to the Pittsburg Dispatch, the largest and most important contract for aluminum ever made has just been closed by the Pittsburg Reduction Company. The contract calls for the delivery in London to the British Aluminum Company of 1,080 tons of aluminum casting ingots at a price aggregating over $750,000. The largest previous contract was one of 80 tons, made some time ago with the German government. This makes Pittsburg the greatest producing center of aluminum in the world. According to the contract, the aluminum will be delivered at the rate of 25 tons per month for the first two years and 20 tons per month for the ensuing two years. The British Aluminum Company has been considered one of the greatest producers of aluminum in Europe, and the placing of such a large contract in the United States is looked upon as significant. The exporting of such great quantities is due to the ingenuity and enterprise of American manufacturers, and places this country at once in the lead of the world. President Alfred E. Hunt, of the Pittsburg Reduction Company, A. W. Mellon, a heavy stockholder in the concern, and J. O. Handy, the principal chemist, are now in Europe, supposedly in connection with the big contract. While the plant of the company is located at Niagara Falls, it is owned by Pittsburgers, and immense benefits are expected to accrue to that city. It is understood the largest part of this shipment of metal will be used for army utensils and buckles for the Russian army.

PRODUCTION OF STATUARY.

THE first thing to settle in a statue or group is the general design. For this purpose the artist, having chosen his subject, makes one or more sketches on paper, representing his conception of the treatment appropriate to it; these he will vary as improvements on the original idea suggest themselves, or as new notions spring up. Having to a certain extent satisfied himself with one or other of them, as expressing fully what he wishes, and as being at the same time harmonious in its arrangement, he then proceeds to make from it a small sketch or model in clay, in order to ascertain its probable effect in other views than the one represented on the paper. For it must be recollected that sculpture is widely different from its sister art, painting; the former has many views to consider, the latter has but one; and though in a piece of sculpture there will, of course, be principal views more effective than others, still they must all be agreeable, and to a certain extent suggestive or expressive of the main idea; and for this reason the sculptor has frequently to sacrifice or modify that which, were only one view to be considered, would aid him forcibly in his intentions. It is scarcely necessary to say, therefore, that alterations occur again in these clay sketches, and more than one is frequently made before the final decision on the question of design takes place. This done, the full size model is commenced in clay, the same material as the sketch, and for this the artist has to supply supports, as it rarely happens, except in recumbent figures, that the clay will hold itself together in the required position without their aid; no difficulty exists, however, in providing these, the roughest hedge carpentering answering the purpose better than the finest workmanship. All that has to be done is to build up upon the stool a rough woodwork of sufficient strength to bear the weight of the clay and prevent it sinking, and to so arrange it that it shall be contained within the surface of the proposed model. Upon this the clay is kneaded by the hand into the requisite form, unassisted by anything but a few very simple wooden tools that help to cut, scrape or press, as may be required. The clay itself is that prepared by the potters for the common white stoneware, and is in no way expensive. Young inexperienced artists often show an overstrong predilection for the use of these wooden spatulas, or modeling tools, as by their assistance they find they can more easily obtain a smooth surface to their work; but experience afterward teaches them that an imitation of the pulpy surface of the flesh can only be obtained from the touch of flesh itself, or, in other words, from the pressure of the finger and thumb, and that the wooden tools must be used sparingly, merely as assistants to the hand, otherwise a hard mechanical style is apt to creep in. There is in truth in a real artist, when working on his clay, the same species of feeling as in a fine pianoforte player, who draws expression from the instrument, not barely from correctness of note, but from a mental absorption in the music which imparts itself to his touch, and this affinity between head and hand is interrupted in the sculptor when the modeling tool intervenes between the surface of his work and the delicate sensation with which his hands are endowed.

With persons unacquainted with sculpture there is a general impression that the cutting of the marble is the most difficult part; but those who are intimate with the art know that the designing and modelling are the primary portions, and that the other, though of course requiring some knowledge as well as taste, is, in comparison, scarcely more than a clever manual dexterity. The artist, in fact, employs his own hand almost entirely on the designs and modeling, for in these stages he has to originate almost all the beauties of his work, and he knows if his model be in any way defective, inaccurate in its proportions or wanting in beauty or expression, that there is no hope that such defects will be remedied in the marble. The latter portion is indeed, in a measure, a mechanical process of copying, restricted, by the very means it employs, from departing to any great extent from the model. Before the model is finished nature must be referred to, and that frequently, to give an air of truth to the figure, which never was and never will be gained except by reference to her. We will, however, suppose that the sculptor has by dint of time and labor thoroughly studied his model, compared it with and corrected it from nature, arranged his draperies and subordinate parts in proper order, brought all the surfaces up to a necessary degree of smoothness, in fact, given to the best of his talent and power actual embodiment of that which his mind has conceived. It is still in the soft clay, which will not bear moving, nor be durable for long, as it is liable to shrinking, and if not constantly supplied with moisture would eventually crack, owing to the supports within not allowing every part to diminish in an equal degree. It has for this reason to be moulded and cast into plaster, a process we shall briefly describe. Plaster of Paris is a strong, fine, white lime, made from gypsum or alabaster ground to powder and baked; and, so prepared, has the property of crystallizing rapidly when mixed with water, or, in other words, of condensing itself into a hard body. A certain quantity is mixed with water, sufficient to form a liquid of about the consistency of good cream, and thrown over a portion of the model, walls of soft clay having been built round that portion in order to prevent it from running on the other parts. The object of thus covering a part only at a time will be seen presently, and the proper division of such parts must be learned by experience, as it depends entirely upon the peculiarities of the model. This liquid plaster of Paris will, under the hands of an experienced workman, take an exact impression of the surface, and in the course of a few minutes become hard, as we have before explained. More must be added, however, in order to render it of the thickness necessary to sustain itself, which thickness will depend on the size of the object to be moulded. The clay walls are then removed, when we have one-half or more of the model covered with a hard shell, the edges of which stand up clean and square from the clay. These edges are then soiled with clay water, and the same process goes on with the other half; or, if it be a very complicated work, there may perhaps be three, four, or even five pieces of mould, all made in this way in succession.

The whole having been covered, after this manner, with a coating, the inner surface of which has taken a delicate impression of every marking on the model, the next step is to open this shell or mould, in order to take out the clay. If the joints between the pieces have been well washed with clay water, these will separate easily by the driving in, at judicious distances, of a few wooden wedges. At any rate, one piece will come away by this means, and from the opening thus made we can pick out the clay, just as it will best come, only taking care not to injure the surface of the mould, as any damage done to that will show itself in the cast. The interior of the mould is now washed with a soft brush and water, and the pieces again put together and bound round with ropes to keep them to their places. The whole is well saturated with water, and fresh plaster of Paris of a finer quality poured into it through the mouth formed by the underneath side of the base. This also, becoming in a few minutes hard, forms a facsimile in plaster of the clay model, to be afterward extracted from the outer casing or mould. Between the surfaces of the two, however, there is but little adhesion, as the saturating the first with water previous to filling it with the second prevents it. The removing the outer coating is accomplished by chipping it off in small pieces by means of a mallet and blunt chisel. This part of the work requires considerable practice as well as caution to prevent injuring the cast; but if everything has been well managed, the pieces will splinter off before the edge of the chisel reaches it. To remedy at last any little faults or inaccuracies that may have occurred, rasps, glass paper, fish skin and for small work Dutch rush are used.

The working of the marble now begins, which, if it require not the highest talent, takes at least the longest time and the greatest labor. The model and marble are fastened in relative positions on two square blocks of stone, having each, along the edge in front, a scale of parts marked out, similar to those on a carpenter's rule. The "pointing instrument," as it is called, is then applied, which consists generally of an upright pole, with a cross piece attached, that travels along the edge so marked, just as a T-square travels along the edge of a drawing board. (This pointing instrument may indeed be well conceived by fancying a large T-square, the long part round instead of flat and perpendicular instead of horizontal.) To this is attached a circular metal bar, and at the end of that again a needle, with ball and socket joints between both. By the aid of these joints the workman can fix the point of the needle to any part of his model, and having by means of the screws tightened the joints, can transfer the instrument from the stone on which the model rests to the other, when of course the relative position of that part in the marble will be indicated if the instrument itself be fixed to the corresponding number on the scale. It is, in fact, nothing more than a system of finding a third point from two already given. Various improvements have from time to time been made on this instrument in order to gain facility of motion, but the principle in all is the same. The best one is, perhaps, that invented by Behnes, for which the Society of Arts awarded its gold medal. It possesses greater variety of movement than any other, and, as such, is more convenient to the workman, but has one drawback—a too great liability to get out of repair. Indeed, it will be easily understood that in an operation where dust and small pieces of marble are constantly flying about, it is not advisable to have to do with machinery of too delicate a construction. By this simple method the block is hewn out roughly, but correctly, into shape, and a great number of points or perforations are made in it, the bottom of which represent the surface of the model, and correspond in distance from each other with small pencil dots, marked at the time of taking them upon the model. These marks on marble and model form so many guides for the carver who now takes the work in hand, so that his mind is entirely relieved from the apprehension of any error in the main proportions or position of parts, these being definitely fixed by the points themselves. He has merely to copy what he sees correctly, by the aid of these points, and to bring the whole to a good fine surface; his ingenuity is displayed in clearing out with his chisel and hand drill the deep cuttings—often a very difficult task, attended not only with a great deal of labor, but requiring considerable skill as well as practice. The marble comes at last again into the artist's studio, from whence the model emanated; and his delight is then in giving those final touches which remove from it any hardness or immobility it may have acquired under the hands of a copier and impart to it the spirit and character of nature. The whole is ultimately rubbed over with sand and water by the aid of small pieces of wood and linen rags, to remove the dry, dusty appearance derived from the chisel or rasp and to bring up the lucid beauty of the material.

When the multiplying of casts is required, as is frequently the case, a mould is again made upon the finished marble, much after the fashion previously described with the clay, but composed of an immense number of pieces, fitting one within the other, so as to admit of each one coming away separately from the marble, and, again, from the casts, without injury to either.

This is professionally termed "safe moulding," on account of the outer coating being preserved; in opposition to the other, which is called "waste moulding," from the shell or mould being destroyed in the process. Any reasonable number of casts may be taken from the safe moulds.

Bronze casting is another distinct process, little understood by artists themselves, and requiring, moreover, considerable accommodation in the way of premises, furnaces, apparatus, etc. For these reasons it is frequently intrusted to regular trade founders, who understand well enough the moulding and melting of metals, but who cannot be expected to comprehend the niceties required in a good work of art. The consequence is, in this country at least, that considerable deterioration often takes place; the bronze casting representing but imperfectly the form of the original model. The practice in these ordinary foundries is to mould the parts of a statue in sand and loam, after the manner of common metal castings, and without doubt much expense is thereby saved; but the result is never quite satisfactory, as these materials are not fine enough to take a sharp expression, nor stable enough to retain it uninjured during the operation of building the core and pouring the metal, owing to which many parts of the mould have to be repaired by the workman, and accuracy to the model is lost. In engineer's work castings are all afterward made true by planing, turning, filing, etc., so that, provided they be sound, it is not positively necessary that they should be in every respect accurate. Not so with fine art bronzes. Chasing—in fact, all tool work on the metal—tends to destroy all freedom of manipulation, and to produce in its stead a stiff, mechanical style, the reverse of all semblance to flexibility. It is desirable, therefore, that a bronze statue should be cast from the mould as perfect as can be, and that it be subject as little as possible to the operation of the chaser's chisels and punches, though of course these must be brought into use, to a certain extent, as matters of necessity rather than choice.

Moulding for bronze requires frequently that the plaster model should be cut into parts. It rarely happens, in fact, that a statue or group can be cast in one piece, owing to difficulties that arise, first from the moulding itself, and secondly from the running of the metal into that mould. It will not be requisite to describe the moulding of these pieces, as the process is similar to that previously performed on the clay, with some modifications necessary to suit the nature of metals. There are, however, two or three points which require especial care and attention, and which regulate many of the contrivances adopted in it, and by alluding to these we shall at once enable the reader, aided by what has already been said, to understand the whole business. One of them is the necessity for fully providing for the free entrance of the liquid metal into the mould, as well as for the easy and perfect escape of the air out of it, as it becomes displaced by the metal; for, without proper arrangement for this there is not the slightest chance of the cast being sound, and explosions may take place, destructive not only of the work, but even of life itself. For this reason channels have to be made in the joints of the mould down which the metal is first made to run, whence, entering the vacancy left to form the cast at the lowest point, it rises upward through all the parts, and the air can thus easily escape through other channels cut for that purpose. It should be here mentioned for the benefit of those unacquainted with the nature of metal casting that there must always be provided an inner mould, or as it is termed a core, to regulate the thickness of the metal. This is managed by laying on the surface of the outer mould clay of the required thickness, and then filling up the interior with the same material as the mould itself, after which the outer mould is removed and the clay taken away, leaving the necessary vacancy for the metal between the two when they are again put together. The material to form the mould and core must be of a consistency to retain the impression given to it from the model, of a nature to resist the action of the hot metal and sufficiently porous to allow the escape of gas, without which the liquid fire will not settle quietly and soundly down on its surface. Sand moulds act well as far as the last two are concerned, but are too fragile for the complicated forms of statue moulding, and experience has taught us that a mixture in equal proportions of plaster of Paris and brickdust serves best all purposes, the former giving it consistency and the latter answering all desiderata with regard to the metal. These brickdust and plaster moulds are, of course, tender, and must, therefore, be duly supported with irons embedded within them, as well as built upon iron basements, to enable them to be lifted about without injury by means of cranes. When complete they are bound round by iron hoops, and put into an oven to dry for five or six weeks, according to their size. Care in this particular is highly important, as the least damp will cause a bubbling or disturbance of the metal as it runs in. At the end of this time, when the casting takes place, the mould is lowered into a pit prepared for the purpose, and tightly embedded in sand. Weights are put upon the top to prevent the uprising of any part as the metal enters. Every precaution, in fact, is taken against expansion. Channels are then made of sand from the orifice of the furnace to the mouth of the mould; the furnace is tapped, and the liquid flame rushes out through the roads so formed for it. This is the anxious moment upon which the result of many weeks' work depends. If the metal run quietly down the mould, and appear again up the passages formed for the escape of the air, it is but reasonable to infer that it has traveled through every part, and that a good cast will be the result. But if by chance a beautiful jet-de-feu takes place, reaching almost to the foundry roof, it may be as well to retire to a respectful distance, notwithstanding that the dispersion of so much valuable metal may create a desire to see where it falls. The moulder, too, may recommence his work immediately, for waiting until to-morrow, when the mould and cast are to be dug out of the pit, will be scarcely worth while.

No bronze mould can serve for more than once, and the cast will be found to have a strong resemblance to a honeycomb, very curious, no doubt, but not exactly suited to display clear definition of form. Such noisy and expensive fireworks do not, however, take place in a well managed affair, where there is everything proper for use and every care taken. But the mention of them may serve to caution those who have not the means at hand to do what is right, or who meddle with the process without the necessary knowledge or experience to guide them. Some variety of opinion exists on the question of what this metal called bronze should be composed; but the late Mr. Maudsley, no mean authority, declared 91 of copper to 9 of tin to be the best mixture for figure casting, and his opinion has certainly been found correct. An addition of about one and a half of zinc, put in when the copper is melted, makes it flow more freely. But a greater quantity than this is scarcely justifiable, as zinc is liable to be acted upon by acids, and, if used too freely, may endanger the durability of the statue. The mould comes off from the cast in dry dust, as does also the core from the inside. The parts called runners, formed on the cast by the metal filling up the passages through which it has flowed, and the projecting lines, caused by the seams or joints, have then to be cut off, and any little defects remedied by the chasing tools. The whole should then be scrubbed with emery and water to remove a green scurf attached to it, the presence of which is, however, a sure indication of a good surface beneath. The last proceeding is to join the various parts so cast. This is done by first fastening them together by bolts, and then pouring hot metal from a crucible over the joint,

POLAR BEARS FIGHTING.

6 or 7 inches at a time, when embedded in sand so as to expose nothing but the edges required to be united. When cool this leaves a piece of metal standing up, to be afterward cut away. A repetition of this operation, all along the joint, will be found to unite the parts as solidly as if cast at one time, and will not be at all visible in the finished work. The statue is then complete. Attempts, it is true, are sometimes made to give an artificial color to the metal, by means of acids, before it leaves the foundry; but time does that better than anything else.—The Architect and Contract Reporter.

A FIGHT OF POLAR BEARS.

THE scene brought before us in our illustration shows an intensely critical moment. Two polar bears have attacked each other in a quarrel, probably over some morsel of food, and in their struggle have rolled to the edge of their bath. Here the bear who has secured the upper hand holds the apparently weaker one gripped by the throat and plunges him heavily into the familiar element. The conqueror has his vanquished foe practically at his mercy, nor does the fierce glow of his eyes speak of sparing pity.

Meanwhile the noise of the conflict has called the keepers to the spot, and, dreading the loss of one of their finest specimens, they exert all that is in their power to separate the furious beasts. Poles, spikes, large pieces of timber and heavy stones are the most handy means of distracting the bears' attention from their private enmity. It seems, indeed, that the stone which is just flying in midair at the moment which our cut represents must needs make some impression on the combatant it is aimed at. However, here lies the critical question, the thread on which hangs the fate of the victim. We leave it to our readers to decide whether it shall live or die.

The whole scene carries an impression of giant strength let loose, of huge masses tossed by irresistible powers. This effect is yet heightened by the clumsy bulk of the bears' bodies, their fiercely sparkling eyes and the gaping mouth beset with fearful teeth of the defeated foe.—For our engraving we are indebted to Der Zoologische Garten.

A HAND-SHAPED CARROT.

WE reproduce herewith, from La Nature, a figure of a vegetable curiosity in the form of a hand-shaped carrot which was gathered by a farmer at Boisnithum, near Boulogne-sur-Mer. It will be remarked that the five fingers of the hand are clearly delineated. Some of them doubtless, such as the index and middle finger, have a somewhat irregular form, but there neverthe-

HAND-SHAPED CARROT.

less exist proportions among all of them that make them resemble the fingers of the human hand.

COMMON PLANTS.

EVERY nurseryman's catalogue gives an important place to its list of rare plants, and, of course, the prices of trees and shrubs and herbs which are scarce are higher than those which afford an ample stock to draw upon. This is simply in obedience to the law of supply and demand, which in a general way regulates the prices of every commodity which man desires for use or ornament. In the eye of some persons, however, rare plants are invested with a value which does not belong to them intrinsically. One who has acquired the habit or passion for collecting places the highest value on objects which are unique. A first edition or the only known copy of a book which in itself is nearly worthless may be a prize for which a book collector will give a small fortune; and in the same way an orchid which is the only individual of its species known will command a price quite out of proportion to any charm it may have of form or color or fragrance. The case of one who is studying a given genus of plants is somewhat similar. He may want an iris, for example, to complete his series, and to him the missing plant has an importance that would not belong to it under any other conditions.

All this is readily comprehensible, but there are other people who have a feeling somehow that rarity is in itself an element of beauty in a plant; at all events, if they would not state this broadly, they firmly believe in its converse, namely, that a plant which is common is not desirable. It is this idea which lies at the root of the distinction between "common trees" and "ornamental trees" which we so often hear. This notion was once so prevalent that it was a difficult thing a few years ago to find common American forest trees and shrubs for sale in American nurseries. When Central Park was planted it was easy enough to buy European birches, Norway maples and horse-chestnuts, but few nurseries had our own canoe birch or pin oak or pepperidge. English hawthorns could be had by the hundred, but many of our native thorns were not propagated at all. Spireas and Kerrias and honeysuckles from abroad could be had by the thousand, but our native honeysuckles and many of the best of the Viburnums and other American shrubs were not classed as ornamental plants at all. Conditions have changed since then somewhat, and the herbaceous plants and shrubs and trees which grow in our own forests and along our waysides have been more freely admitted into the aristocratic society of their foreign relatives, and the fact that a plant is common is not always a reproach to it.

A PLANT OF NEPENTHES × TIVEYI—PITCHERS COLORED BROWN AND GREEN.

Different plants have different values to planters according to the use that is made of them. Landscape gardening wherever it is practiced over areas of considerable extent deals properly with scenery: that is, with the permanent features of the land—its roll of surface, its sky-line and distance. The greatest artist in landscape is one who with these fundamental elements and the common trees and shrubs and grass makes a picture which is a unit, and every portion of which helps consistently to give expression to a central idea. This differs entirely from what is called decorative gardening, which is concerned more especially with the detailed ornamentation of more limited spaces. For decorative purposes plants and flowers may be grouped into arrangements which kindle admiration on account of their symmetry of form and richness of color. This is the presentation of beauty for its own sake. It appeals to the æsthetic sense alone and not to the imagination, and through it to our higher nature as a landscape picture does. It is not necessary that a decorative group should be in any sense natural, and plants with foliage of strong color or those that can be trained into peculiar shapes or which have an unusual habit are often the most valuable in such places. They are useful just as stones of different form and color are useful in a mosaic. In decorative gardening a plant of golden elder or of Prunus pissardii may have the highest value, while the same plants in a natural landscape would be worse than useless, and, indeed, might ruin a quiet picture by their obtrusiveness.

There is another kind of gardening, however, which has been called specimen gardening, and which has many attractions to lovers of plants. To such persons a garden exists for its plants rather than the plants for the garden. It is not a landscape picture that is desired, nor yet geometrical designs of pleasing form and color. It is individual plants that are cherished irrespective of their arrangement, and they may be selected for their rarity or their oddity, or for any other quality that appeals to the fancy of the planter. This makes a pleasant diversion, but it is by no means the highest form of gardening. A wise observer once said that it marked a distinct decline in garden art when a gentleman led you to a point on his estate where he could show you the finest Cryptomeria in England, instead of conducting you to the point where you might see the most delightful view.

But we have wandered from our purpose. We set out to make a mild protest against the idea that a plant is not desirable if it is common. A great patron of horticulture once declared that he could get up no enthusiasm for lilacs because they could be seen at every farm-house door. Now, since there are hundreds of varieties of the common lilac and many distinct species besides, there is opportunity for gathering a collection of these shrubs, which represent a wide diversity of habit as well as in the form and color of their flowers—many of them rare plants which never graced a farmer's yard. But the common lilac itself will always be a desirable shrub. It has such intrinsic merit that it cannot be vulgarized by mere abundance. Its habit of growth, the graceful way in which its dense panicles of flowers are carried above the thick leaves, their exquisite color, which has no exact duplicate in the vegetable kingdom; the fragrance, which is their own and unmistakable, will always make this a useful plant. It is hardy, long-lived, and will endure abuse; it is often found by a wayside cabin without a single companion, and yet it is beautiful enough to have been the chief ornament of the home of one of our great poets. It is admired because of its many good qualities, and it will be more and more valued for association by every succeeding generation of plant lovers. The fact is, that for all practical purposes the cheapest plants are the best. Among the novel introductions every year there are some that will stand the test of time, and as soon as they demonstrate their usefulness they will be common. In order to be widely useful a plant must be easily propagated, it must be hardy and long-lived, and these are qualities that will ultimately make it cheap, just as the Tartarian honeysuckle is cheap, although one of the most beautiful and indispensable of shrubs. Grass is common, but it is an unfailing refreshment to the eye, and it is so universally appreciated that no one considers Ruskin's glowing description pitched on too high a key. No novice need be deterred from planting trees or shrubs on account of the high price of novelties or rarities. If his purse will allow him to import the most expensive sorts, he may find pleasure in gratifying his desires in this direction, but if he buys no others he will discover at last that he has but a sickly lot of incongruities. He will learn that the common plants are the basis of every good collection, and that cheap plants are the most effective in producing pictures which are impressive and permanent.—Garden and Forest.

NEPENTHES × TIVEYI.

OUR illustrations represent a full-sized pitcher and the plant as it appears at the present time, of a new hybrid of Nepenthes raised at the Royal Exotic Nursery, Chelsea, and exhibited at the Royal Horticultural Society's meeting held at Westminster. The plant is

PITCHER OF NEPENTHES × TIVEYI.

the result of a cross between the species N. Curtisii and N. Veitchi. The ground color of the body of the pitcher is of a light green, streaked and blotched with a bright brown tint, as is likewise the prolongation of the midrib of the leaf on which the pitcher depends. A conspicuous feature is the broad, convex rim of the pitcher, which is of bright reddish brown, running into

a lighter shade toward the inner edge, and beautifully lined. The operculum or lid resembles the rest of the pitcher in regard to the ground color and markings; the wings are green, and possess a few long hairs. The pitchers in general partake of the characteristics of both parents—N. Veitchi, a Bornean species of great beauty, going sometimes under the names of villosa and sanguinea. We are indebted to the Gardeners' Chronicle for the cuts and particulars.

AN UNDISCOVERED GAS.*

By Prof. WILLIAM RAMSAY, Ph.D., LL.D., Sc.D., F.R.S.

THE subject of my remarks to-day is a new gas. I shall describe to you later its curious properties; but it would be unfair not to put you at once in possession of the knowledge of its most remarkable property—it has not yet been discovered. As it is still unborn, it has not yet been named. The naming of a new element is no easy matter. For there are only twenty-six letters in our alphabet, and there are already over seventy elements. To select a name expressible by a symbol which has not already been claimed for one of the known elements is difficult, and the difficulty is enhanced when it is at the same time required to select a name which shall be descriptive of the properties (or want of properties) of the element. It is now my task to bring before you the evidence for the existence of this undiscovered element.

It was noticed by Döbereiner, as long ago as 1817, that certain elements could be arranged in groups of three. The choice of the elements selected to form these triads was made on account of their analogous properties, and on the sequence of their atomic weights, which had at that time only recently been discovered. Thus calcium, strontium and barium formed such a group; their oxides, lime, strontia, and baryta, are all easily slaked, combining with water to form soluble lime water, strontia water and baryta water. Their sulphates are all sparingly soluble, and resemblance had been noticed between their respective chlorides and between their nitrates. Regularity was also displayed by their atomic weights. The numbers then accepted were 20, 42·5 and 65; and the atomic weight of strontium, 42·5, is the arithmetical mean of those of the other two elements, for (65 + 20)/2 = 42·5. The existence of other similar groups of three was pointed out by Döbereiner, and such groups became known as "Döbereiner's triads."

Another method of classifying the elements, also depending on their atomic weights, was suggested by Pettenkofer, and afterward elaborated by Kremers, Gladstone and Cooke. It consisted in seeking for some expression which would represent the differences between the atomic weights of certain allied elements. Thus the difference between the atomic weight of lithium, 7, and sodium, 23, is 16; and between that of sodium and of potassium, 39, is also 16. The regularity is not always so conspicuous. Dumas, in 1857, contrived a somewhat complicated expression which, to some extent, exhibited regularity in the atomic weights of fluorine, chlorine, bromine and iodine; and also of nitrogen, phosphorus, arsenic, antimony and bismuth.

The upshot of these efforts to discover regularity was that, in 1864, Mr. John Newlands, having arranged the elements in eight groups, found that when placed in the order of their atomic weights, "the eighth element, starting from a given one, is a kind of repetition of the first, like the eighth note of an octave in music." To this regularity he gave the name "The law of octaves."

The development of this idea, as all chemists know, was due to the late Prof. Lothar Meyer, of Tübingen, and to Prof. Mendeleeff, of St. Petersburg. It is generally known as the "Periodic Law." One of the simplest methods of showing this arrangement is by means of a cylinder divided into eight segments by lines drawn parallel to its axis; a spiral line is then traced round the cylinder, which will, of course, be cut by these lines eight times at each revolution. Holding the cylinder vertically, the name and atomic weight of an element is written at each intersection of the spiral with a vertical line, following the numerical order of the atomic weights. It will be found, according to Lothar Meyer and Mendeleeff, that the elements grouped down each of the vertical lines form a natural class; they possess similar properties, form similar compounds, and exhibit a graded relationship between their densities, melting points and many of their other properties. One of these vertical columns, however, differs from the others, inasmuch as on it there are three groups, each consisting of three elements with approximately equal atomic weights. The elements in question are iron, cobalt and nickel; palladium, rhodium and ruthenium; and platinum, iridium and osmium. There is apparently room for a fourth group of three elements in this column, and it may be a fifth. And the discovery of such a group is not unlikely, for when this table was first drawn up Prof. Mendeleeff drew attention to certain gaps, which have since been filled up by the discovery of gallium, germanium and others.

The discovery of argon at once raised the curiosity of Lord Rayleigh and myself as to its position in this table. With a density of nearly twenty, if a diatomic gas, like oxygen and nitrogen, it would follow fluorine in the periodic table; and our first idea was that argon was probably a mixture of three gases, all of which possessed nearly the same atomic weights, like iron, cobalt and nickel. Indeed, their names were suggested, on this supposition, with patriotic bias, as Anglium, Scotium and Hibernium! But when the ratio of its specific heats had, at least in our opinion, unmistakably shown that it was molecularly monatomic, and not diatomic, as at first conjectured, it was necessary to believe that its atomic weight was 40, and not 20, and that it followed chlorine in the atomic table, and not fluorine. But here arises a difficulty. The atomic weight of chlorine is 35·5 and that of potassium, the next element in order in the table, is 39·1; and that of argon, 40, follows, and does not precede, that of potassium, as it might be expected to do. It still remains possible that argon, instead of consisting wholly of monatomic molecules, may contain a small percentage of diatomic molecules; but the evidence in favor of this supposition is, in my opinion, far from strong. Another possibility is that argon, as at first conjectured, may consist of a mixture of more than one element; but, unless the atomic weight of one of the elements in the supposed mixture is very high, say 82, the case is not bettered, for one of the elements in the supposed trio would still have a higher atomic weight than potassium. And very careful experiments, carried out by Dr. Norman Collie and myself, on the fractional diffusion of argon, have disproved the existence of any such element with high atomic weight in argon, and indeed have practically demonstrated that argon is a simple substance, and not a mixture.

The discovery of helium has thrown a new light on this subject. Helium, it will be remembered, is evolved on heating certain minerals, notably those containing uranium; although it appears to be contained in others in which uranium is not present, except in traces. Among these minerals are cleveite, monazite, fergusonite, and a host of similar complex mixtures, all containing rare elements, such as niobium, tantalum, yttrium, cerium, etc. The spectrum of helium is characterized by a remarkably brilliant yellow line, which had been observed as long ago as 1868 by Profs. Frankland and Lockyer in the spectrum of the sun's chromosphere, and named "helium" at that early date.

The density of helium proved to be very close to 2·0, and like argon, the ratio of its specific heat showed that it, too, was a monatomic gas. Its atomic weight therefore is identical with its molecular weight, viz., 4·0, and its place in the periodic table is between hydrogen and lithium, the atomic weight of which is 7·0.

The difference between the atomic weights of helium and argon is thus 36, or 40—4. Now there are several cases of such a difference. For instance, in the group the first member of which is fluorine we have—

Fluorine	19	
Chlorine	35·5	16·5 19·5
Manganese	55	

In the oxygen group—

Oxygen	16	
Sulphur	32	16 20·3
Chromium	52·3	

In the nitrogen group—

Nitrogen	14	
Phosphorus	31	17 20·4
Vanadium	51·4	

And in the carbon group—

Carbon	12	
Silicon	28·3	16·3 19·8
Titanium	48·1	

These instances suffice to show that approximately the differences are 16 and 20 between consecutive members of the corresponding groups of elements. The total differences between the extreme members of the short series mentioned are—

Manganese—fluorine	36
Chromium—oxygen	36·3
Vanadium—nitrogen	37·4
Titanium—carbon	36·1

This is approximately the difference between the atomic weights of helium and argon, 36.

There should, therefore, be an undiscovered element between helium and argon, with an atomic weight 16 units higher than that of helium, and 20 units lower than that of argon, namely, 20. And if this unknown element, like helium and argon, should prove to consist of monatomic molecules, then its density should be half its atomic weight, 10. And pushing the analogy still farther, it is to be expected that this element should be as indifferent to union with other elements as the two allied elements.

My assistant, Mr. Morris Travers, has indefatigably aided me in a search for this unknown gas. There is a proverb about looking for a needle in a haystack; modern science, with the aid of suitable magnetic appliances, would, if the reward were sufficient, make short work of that proverbial needle. But here is a supposed unknown gas, endowed no doubt with negative properties, and the whole world to find it in. Still, the attempt had to be made.

We first directed our attention to the sources of helium—minerals. Almost every mineral which we could obtain was heated in a vacuum, and the gas which was evolved examined. The results are interesting. Most minerals give off gas when heated, and the gas contains, as a rule, a considerable amount of hydrogen, mixed with carbonic acid, questionable traces of nitrogen, and carbonic oxide. Many of the minerals, in addition, gave helium, which proved to be widely distributed, though only in minute proportion. One mineral—malacone—gave appreciable quantities of argon; and it is noteworthy that argon was not found except in it (and, curiously, in much larger amount than helium) and in a specimen of meteoric iron. Other specimens of meteoric iron were examined, but were found to contain mainly hydrogen, with no trace of either argon or helium. It is probable that the sources of meteorites might be traced in this manner, and that each could be relegated to its particular swarm.

Among the minerals examined was one to which our attention had been directed by Prof. Lockyer, named eliasite, from which he said that he had extracted a gas in which he had observed spectrum lines foreign to helium. He was kind enough to furnish us with a specimen of this mineral, which is exceedingly rare, but the sample which we tested contained nothing but undoubted helium.

During a trip to Iceland in 1895 I collected some gas from the boiling springs there. It consisted, for the most part, of air, but contained somewhat more argon than is usually dissolved when air is shaken with water.

In the spring of 1896 Mr. Travers and I made a trip to the Pyrenees to collect gas from the mineral springs of Cauterets, to which our attention had been directed by Dr. Bouchard, who pointed out that these gases are rich in helium. We examined a number of samples from the various springs, and confirmed Dr. Bouchard's results, but there was no sign of any unknown lines in the spectrum of these gases. Our quest was in vain.

We must now turn to another aspect of the subject. Shortly after the discovery of helium, its spectrum was very carefully examined by Profs. Runge and Paschen, the renowned spectroscopists. The spectrum was photographed, special attention being paid to the invisible portions, termed the "ultra-violet" and "infra-red." The lines thus registered were found to have a harmonic relation to each other. They admitted of division into two sets, each complete in itself. Now, a similar process had been applied to the spectrum of lithium and to that of sodium, and the spectra of these elements gave only one series each. Hence, Profs. Runge and Paschen concluded that the gas, to which the provisional name of helium had been given, was, in reality, a mixture of two gases, closely resembling each other in properties. As we know no other elements with atomic weights between those of hydrogen and lithium, there is no chemical evidence either for or against this supposition. Prof. Runge supposed that he had obtained evidence of the separation of these imagined elements from each other by means of diffusion; but Mr. Travers and I pointed out that the same alteration of spectrum, which was apparently produced by diffusion, could also be caused by altering the pressure of the gas in the vacuum tube; and shortly after Prof. Runge acknowledged his mistake.

These considerations, however, made it desirable to subject helium to systematic diffusion, in the same way as argon had been tried. The experiments were carried out in the summer of 1896 by Dr. Collie and myself. The result was encouraging. It was found possible to separate helium into two portions of different rates of diffusion, and consequently of different density, by this means. The limits of separation, however, were not very great. On the one hand, we obtained gas of a density close on 2·0; and on the other, a sample of density 2·4 or thereabout. The difficulty was increased by the curious behavior, which we have often had occasion to confirm, that helium possesses a rate of diffusion too rapid for its density. Thus, the density of the lightest portion of the diffused gas, calculated from its rate of diffusion, was 1·874; but this corresponds to a real density of about 2·0. After our paper, giving an account of these experiments, had been published, a German investigator, Herr A. Hagenbach, repeated our work and confirmed our results.

The two samples of gas of different density differ also in other properties. Different transparent substances differ in the rate at which they allow light to pass through them. Thus, light travels through water at a much slower rate than through air, and at a slower rate through air than through hydrogen. Now Lord Rayleigh found that helium offers less opposition to the passage of light than any other substance does, and the heavier of the two portions into which helium had been split offered more opposition than the lighter portion. And the retardation of the light, unlike what has usually been observed, was nearly proportional to the densities of the samples. The spectrum of these two samples did not differ in the minutest particular; therefore it did not appear quite out of the question to hazard the speculation that the process of diffusion was instrumental, not necessarily in separating two kinds of gas from each other, but actually in removing light molecules of the same kind from heavy molecules. This idea is not new. It had been advanced by Prof. Schützenberger (whose recent death all chemists have to deplore), and later by Mr. Crookes, that what we term the atomic weight of an element is a mean; that when we say that the atomic weight of oxygen is 16, we merely state that the average atomic weight is 16; and it is not inconceivable that a certain number of molecules have a weight somewhat higher than 32, while a certain number have a lower weight.

We therefore thought it necessary to test this question by direct experiment with some known gas; and we chose nitrogen, as a good material with which to test the point. A much larger and more convenient apparatus for diffusing gases was built by Mr. Travers and myself, and a set of systematic diffusions of nitrogen was carried out. After thirty rounds, corresponding to 180 diffusions, the density of the nitrogen was unaltered, and that of the portion which should have diffused most slowly, had there been any difference in rate, was identical with that of the most quickly diffusing portion, i. e., with that of the portion which passed first through the porous plug. This attempt, therefore, was unsuccessful; but it was worth carrying out, for it is now certain that it is not possible to separate a gas of undoubted chemical unity into portions of different density by diffusion. And these experiments rendered it exceedingly improbable that the difference in density of the two fractions of helium was due to separation of light molecules of helium from heavy molecules.

The apparatus used for diffusion had a capacity of about two liters. It was filled with helium, and the operation of diffusion was carried through thirty times. There were six reservoirs, each full of gas, and each was separated into two by diffusion. To the heavier portion of one lot, the lighter portion of the next was added, and in this manner all six reservoirs were successively passed through the diffusion apparatus. This process was carried out thirty times, each of the six reservoirs having had its gas diffused each time, thus involving 180 diffusions. After this process, the density of the more quickly diffusing gas was reduced to 2·02, while that of the less quickly diffusing had increased to 2·27. The light portion on rediffusion hardly altered in density, while the heavier portion, when divided into three portions by diffusion, showed a considerable difference in density between the first third and the last third.

A similar set of operations was carried out with a fresh quantity of helium, in order to accumulate enough gas to obtain a sufficient quantity for a second series of diffusions. The more quickly diffusing portions of both gases were mixed and rediffused. The density of the lightest portion of these gases was 1·98; and after other fifteen diffusions, the density of the lightest portion had not decreased. The end had been reached; it was not possible to obtain a lighter portion by diffusion. The density of the main body of this gas is therefore 1·98; and its refractivity, air being taken as unity, is 0·1245. The spectrum of this portion does not differ in any respect from the usual spectrum of helium.

As rediffusion does not alter the density or the refractivity of this gas, it is right to suppose that either one definite element has now been isolated; or that if there

* Address before the chemical section of the British Association for the Advancement of Science.

are more elements than one present, they possess the same, or very nearly the same, density and refractivity. There may be a group of elements, say three, like iron, cobalt, and nickel; but there is no proof that this idea is correct, and the simplicity of the spectrum would be an argument against such a supposition. This substance, forming by far the larger part of the whole amount of the gas, must in the present state of our knowledge be regarded as pure helium.

On the other hand, the heavier residue is easily altered in density by rediffusion, and this would imply that it consists of a small quantity of a heavy gas mixed with a large quantity of the light gas. Repeated rediffusion convinced us that there was only a very small amount of the heavy gas present in the mixture. The portion which contained the largest amount of heavy gas was found to have the density 2·275, and its refractive index was found to be 0·1333. On rediffusing this portion of gas until only a trace sufficient to fill a Plücker's tube was left, and then examining the spectrum, no unknown lines could be detected, but, on interposing a jar and spark gap, the well known blue lines of argon became visible; and even without the jar the red lines of argon and the two green groups were distinctly visible. The amount of argon present, calculated from the density, was 1·64 per cent., and from the refractivity 1·14 per cent. The conclusion had therefore to be drawn that the heavy constituent of helium, as it comes off the minerals containing it, is nothing new, but, so far as can be made out, merely a small amount of argon.

If, then, there is a new gas in what is generally termed helium, it is mixed with argon, and it must be present in extremely minute traces. As neither helium nor argon has been induced to form compounds, there does not appear to be any method, other than diffusion, for isolating such a gas, if it exists, and that method has failed in our hands to give any evidence of the existence of such a gas. It by no means follows that the gas does not exist; the only conclusion to be drawn is that we have not yet stumbled on the material which contains it. In fact, the haystack is too large and the needle too inconspicuous. Reference to the periodic table will show that between the elements aluminum and indium there occurs gallium, a substance occurring only in the minutest amount on the earth's surface; and following silicon, and preceding tin, appears the element germanium, a body which has as yet been recognized only in one of the rarest of minerals, argyrodite. Now, the amount of helium in fergusonite, one of the minerals which yields it in reasonable quantity, is only 33 parts by weight in 100,000 of the mineral; and it is not improbable that some other mineral may contain the new gas in even more minute proportion. If, however, it is accompanied in its still undiscovered source by argon and helium, it will be a work of extreme difficulty to effect a separation from these gases.

In these remarks it has been assumed that the new gas will resemble argon and helium in being indifferent to the action of reagents, and in not forming compounds. This supposition is worth examining. In considering it, the analogy with other elements is all that we have to guide us.

We have already paid some attention to several triads of elements. We have seen that the differences in atomic weights between the elements fluorine and manganese, oxygen and chromium, nitrogen and vanadium, carbon and titanium, is in each case approximately the same as that between helium and argon, viz., 36. If elements further back in the periodic table be examined, it is to be noticed that the differences grow less, the smaller the atomic weights. Thus, between boron and scandium, the difference is 33; between beryllium (glucinum) and calcium, 31; and between lithium and potassium, 32. At the same time, we may remark that the elements grow liker each other the lower the atomic weights. Now, helium and argon are very like each other in physical properties. It may be fairly concluded, I think, that in so far they justify their position. Moreover, the pair of elements which show the smallest difference between their atomic weights is beryllium and calcium; there is a somewhat greater difference between lithium and potassium. And it is in accordance with this fragment of regularity that helium and argon show a greater difference. Then again sodium, the middle element of the lithium triad, is very similar in properties both to lithium and potassium; and we might, therefore, expect that the unknown element of the helium series should closely resemble both helium and argon.

Leaving now the consideration of the new element, let us turn our attention to the more general question of the atomic weight of argon, and its anomalous position in the periodic scheme of the elements. The apparent difficulty is this: The atomic weight of argon is 40; it has no power to form compounds, and thus possesses no valency; it must follow chlorine in the periodic table, and precede potassium; but its atomic weight is greater than that of potassium, whereas it is generally contended that the elements should follow each other in the order of their atomic weights. If this contention is correct, argon should have an atomic weight smaller than 40.

Let us examine this contention. Taking the first row of elements, we have:

$$Li = 7,\ Be = 9{\cdot}8,\ B = 11,\ C = 12,\ N = 14,\ O = 16,\ F = 19,\ ? = 20.$$

The differences are:

2·8, 1·2, 1·0, 2·0, 2·0, 3·0, 1·0.

It is obvious that they are irregular. The next row shows similar irregularities. Thus:

$$(? = 20),\ Na = 23,\ Mg = 24{\cdot}3,\ Al = 27,\ Si = 28,\ P = 31,\ S = 32,\ Cl = 35{\cdot}5,\ A = 40.$$

And the differences:

3·0, 1·3, 2·7, 1·0, 3·0, 1·0, 3·5, 4·5.

The same irregularity might be illustrated by a consideration of each succeeding row. Between argon and the next in order, potassium, there is a difference of —0·9; that is to say, argon has a higher atomic weight than potassium by 0·9 unit; whereas it might be expected to have a lower one, seeing that potassium follows argon in the table. Farther on in the table there is a similar discrepancy. The row is as follows:

$$Ag = 108,\ Cd = 112,\ In = 114,\ Sn = 119,\ Sb = 120{\cdot}3,\ Te = 127{\cdot}7,\ I = 127.$$

The differences are:

4·0, 2·0, 5·0, 1·3, 7·2, —0·7.

Here again there is a negative difference between tellurium and iodine. And this apparent discrepancy has led to many and careful redeterminations of the atomic weight of tellurium. Prof. Brauner, indeed, has submitted tellurium to methodical fractionation, with no positive results. All the recent determinations of its atomic weight give practically the same number, 127·7.

Again, there have been almost innumerable attempts to reduce the differences between the atomic weights to regularity, by contriving some formula which will express the numbers which represent the atomic weights, with all their irregularities. Needless to say, such attempts have in no case been successful. Apparent success is always attained at the expense of accuracy, and the numbers reproduced are not those accepted as the true atomic weights. Such attempts, in my opinion, are futile. Still, the human mind does not rest contented in merely chronicling such an irregularity; it strives to understand why such an irregularity should exist. And, in connection with this, there are two matters which call for our consideration. These are: Does some circumstance modify these "combining proportions" which we term "atomic weights"? And is there any reason to suppose that we can modify them at our will? Are they true "constants of Nature," unchangeable, and once for all determined? Or are they constant merely so long as other circumstances, a change in which would modify them, remain unchanged?

In order to understand the real scope of such questions, it is necessary to consider the relation of the "atomic weights" to other magnitudes, and especially to the important quantity termed "energy."

It is known that energy manifests itself under different forms, and that one form of energy is quantitatively convertible into another form, without loss. It is also known that each form of energy is expressible as the product of two factors, one of which has been termed the "intensity factor," and the other the "capacity factor." Prof. Ostwald, in the last edition of his "Allgemeine Chemie," classifies some of these forms of energy as follows:

Kinetic energy is the product of mass into the square of velocity.

Linear energy is the product of length into force.

Surface energy is the product of surface into surface tension.

Volume energy is the product of volume into pressure.

Heat energy is the product of heat capacity (entropy) into temperature.

Electrical energy is the product of electric capacity into potential.

Chemical energy is the product of "atomic weight" into affinity.

In each statement of factors, the "capacity factor" is placed first and the "intensity factor" second.

In considering the "capacity factors," it is noticeable that they may be divided into two classes. The two first kinds of energy, kinetic and linear, are independent of the nature of the material which is subject to the energy. A mass of lead offers as much resistance to a given force, or, in other words, possesses as great inertia, as an equal mass of hydrogen. A mass of iridium, the densest solid, counterbalances an equal mass of lithium, the lightest known solid. On the other hand, surface energy deals with molecules, and not with masses. So does volume energy. The volume energy of two grammes of hydrogen, contained in a vessel of one liter capacity, is equal to that of thirty-two grammes of oxygen at the same temperature, and contained in a vessel of equal size. Equal masses of tin and lead have not equal capacity for heat; but 119 grammes of tin has the same capacity as 207 grammes of lead, that is, equal atomic masses have the same heat capacity. The quantity of electricity conveyed through an electrolyte under equal difference of potential is proportional, not to the mass of the dissolved body, but to its equivalent, that is, to some simple fraction of its atomic weight. And the capacity factor of chemical energy is the atomic weight of the substance subjected to the energy. We see, therefore, that while mass or inertia are important adjuncts of kinetic and linear energies, all other kinds of energy are connected with atomic weights, either directly or indirectly.

Such considerations draw attention to the fact that quantity of matter (assuming that there exists such a carrier of properties as we term "matter") need not necessarily be measured by its inertia, or by gravitational attraction. In fact, the word "mass" has two totally distinct significations. Because we adopt the convention to measure quantity of matter by its mass, the word "mass" has come to denote "quantity of matter." But it is open to anyone to measure a quantity of matter by any other of its energy factors. I may, if I choose, state that those quantities of matter which possess equal capacities for heat are equal; or that "equal numbers of atoms" represent equal quantities of matter. Indeed, we regard the value of material as due rather to what it can do, than to its mass; and we buy food, in the main, on an atomic, or perhaps, a molecular basis, according to its content of albumen. And most articles depend for their value on the amount of food required by the producer or the manufacturer.

The various forms of energy may therefore be classified as those which can be referred to an "atomic" factor and those which possess a "mass" factor. The former are in the majority. And the periodic law is the bridge between them, as yet, an imperfect connection. For the atomic factors, arranged in the order of their masses, display only a partial regularity. It is undoubtedly one of the main problems of physics and chemistry to solve this mystery. What the solution will be is beyond my power of prophecy; whether it is to be found in the influence of some circumstance on the atomic weig[illegible] hitherto regarded as among the most [illegible]ants of nature;" or whether it will tur[illegible] mass and gravitational attraction are influenced [illegible]perature, or by electrical charge, I cannot [illegible] but some means will ultimately be found [illegible] these apparent discrepancies, I firmly believe [illegible] conciliation is necessary, whatever view [illegible] nature of the universe and of its mode [illegible] whatever units we may choose to regard as [illegible] among those which lie at our disposal.

In this address I have endeavored to fulfill my promise to combine a little history, a little actuality and a little prophecy. The history belongs to the Old World. I have endeavored to share passing events with the New; and I will ask you to join with me in the hope that much of the prophecy may meet with its fulfillment on this side of the ocean.

ARE GENIUSES LONG LIVED?

No, says the popular verdict, based not unreasonably on the idea that the drain on the nervous forces which is attendant upon genius is not conducive to longevity. Yes, says a writer, David Lindsay, in the Gentleman's Magazine, basing his answer upon a long array of figures showing the age at death of a large number of the world's most illustrious sons, selected "with strict impartiality," which figures prove that nearly one-half of the greatest geniuses of the world have passed the Psalmist's limit of threescore years and ten. We give below his tables, which, it will be observed, include none of the gentler sex:

MILITARY MEN.

Mr. Lindsay makes the following summary of the tables:

At an age of above 80, 17 per cent. died,
" " 70 to 80, 28 " "
" " 60 to 70, 25 " "
" " 50 to 60, 17 " "
" " under 50, 13 " "

While, therefore, nearly one-half of those whose names appear in the foregoing lists passed the age of seventy, most of their best work, Mr. Lindsay goes on to remark, appeared at a comparatively youthful age. He continues:

"What, then, are the laws that control the age of genius? Why should a Keats die at twenty-four and a Chaucer at seventy-two? Why should philosophers and men who look deeply into the heart of things, and who would naturally be supposed to wear out their vital energy more quickly than other men—why should these be longer lived than musicians?

"To this latter question there is an answer. It is not until after long years of technical training and brain working that such men as Leibnitz and Descartes

blossom out into all their glory of genius; and there are doubtless many great thinkers even now in our midst who may some day astonish the world by the brilliancy of their teachings—but they may first die. With music it is different. Beethoven, while yet in his early infancy, showed unmistakable signs of his natural abilities; when he was a mere youngster he composed works which, to this day, will stand on their own merits. It is the same with every great musician. Granted that he live to reach early manhood, his fame is secured. And at the time when all Europe is ringing with his praises, his science loving brother is toiling in obscurity, not to step forth into the light of popularity for maybe another quarter of a century, or perhaps not at all, for in the meantime, as we have said, he may die.

"It is true that the very greatest masters of all do not usually live out their normal length of days: Napoleon, Cromwell, Shakespeare, Beethoven—none of these passed into old age. But it is hard to define the term 'genius.' If we are to limit it to some score of men, we must then, perhaps, consider that it is incompatible with length of life. If we give the word larger meaning, and honor with it the thousand lesser lights who illumine the page of history, why, then, it would seem to be a healthy thing to be a genius."

Cleaning Beer Pipes.—In cleaning pipes through which beer is run the following precautions should be observed in order that the soda solution used may have its disinfectant effect. The solution should contain 5 to 10 per cent. of soda. It should be in contact with the pipes no less than one-half hour, and the temperature must not be allowed to fall below 80 deg. Centigrade (212 deg. Fah.). The disinfecting action of soda is not very strong. The main value of the process lies in the power soda has of dissolving off the impurities, and so preparing the pipes for further disinfection by steam.—Uhland's Wochenschrift.

THE MANUFACTURE OF TIN PLATES.*

By GEORGE B. HAMMOND, Penarth.

IN accepting the invitation of your council to prepare a paper on the manufacture of tin plates, I am keenly alive to the difficulty of doing justice to a subject which has been so ably dealt with in the interesting papers read before the institute by Mr. Ernest Trubshaw and by the late Mr. P. W. Flower. I venture, however, to undertake the task, as considerable progress has been made in the science and practical mode of manufacture during recent years, and, however unworthy my paper may be in itself, the subject has an important bearing on the steel trade of the country, and claims more than ordinary interest for this district in which you are now meeting, as the neighboring town of Pontypool was the birthplace of the British tin plate trade, about the year 1665, when, under the auspices of the Hanbury family, Mr. Andrew Yarranton made an attempt to establish the manufacture there, on knowledge obtained by him in Saxony, where the trade was at that time in a flourishing condition. Mr. Yarranton's undertaking produced but little results at the time. Other active minds were, however, apparently engaged in the same direction, for it is recorded that one William Chamberlaine took out a patent in the year 1673 for "a newe arte, mistery, or invencon of great use, etc., for plateing and tynning of iron, copper, steele, and brasse, as also for compressing and plateing of all other metalls," which invention related to the use of certain "engines or instruments and wayes and meanes" of tinning and plating iron, etc.; and seventeen years later, in 1691, John Hemingway was granted a patent, owing to influence at the Court of William and Mary, for the sole use for fourteen years of an invention for "makeing of iron plates tynned over, commonly called tynned plates."

This latter patent, though never actively used, was the cause of the industry being abandoned for a time at Pontypool, until, in the year 1720, Major John Hanbury restarted the Pontypool works; but his venture was attended with little success for some years. The method of producing was slow and laborious, the operation being that of flattening out hot slabs of iron under a quick action helve or tilt hammer, the pieces as reduced in thickness being doubled over and piled with other pieces reduced in the same way, the surfaces being sprinkled with powdered coal or charcoal to prevent welding, the hammering being continued until the required size and thickness were obtained. The plates were afterward steeped in a weak solution of sour rye water or vinegar for several days to remove the oxide and other injurious substances formed on the surface of the plates during the operation of forging, and when cleaned, were immersed in a bath of molten tin.

In the year 1728, Major Hanbury and John Payne brought out an invention for rolling sheet iron, and it was found that plates produced by this new method possessed a finer surface, were more uniform in thickness, softer and more pliable in working, and were much esteemed by the consumers of the time.

The trade then spread to some of the neighboring works of Monmouthshire and Glamorganshire, and in some few instances to the other ironmaking districts. The development was gradual, and the production was soon sufficient for the requirements of this country, and the imports from the Continental works ceased. It was not, however, till the present century that the trade made any rapid strides, when, by the advances of science and civilization, the uses to which tin plates may be applied in the canning of fish, fruit, other food stuffs, and oil became known.

The trade, however, gave constantly increasing employment to the laboring classes of South Wales and Monmouthshire, a district which has retained its position as the principal seat of the manufacture for more than 150 years, extending to the present time. Whole families have engaged in the industry in the same localities from generation to generation, until their present representatives, with some reason, look upon the trade as their birthright, and regard with jealous eyes the now rapid growth of the manufacture in other countries, preferring, in times of depression, to follow the trade into distant lands rather than engage in other occupations at home. It is also a noteworthy fact that wherever tin plate works have been established within recent years, Welsh workers have been required to instruct the native labor and to assist in the development of the art. At the present time employment is found in this country for many thousands of workpeople in the industry itself, and many thousands more in those trades which are dependent on providing the materials from which tin plates are produced; one instance of which is the fact that more than half a million tons of British steel bars are annually produced for the purpose, some of our largest steel works being partially, and in some instances wholly, employed in manufacturing this material. The expansion of the trade in this country over the last thirty years has been very marked, and the extent of it may be gathered from the following statistics, taken from the Board of Trade returns, representing the shipments to all countries of the world, and taken at intervals over the period named, but they do not include the plates produced for home consumption, nor—as regards the periods to 1895—the black plate shipped for coating abroad:

Year.	Weight.	Value.	Average Price.
	Tons	£	£
1867	78,906	2,060,410	26·11
1872	118,083	3,896,973	32·94
1877	153,236	3,068,126	19·80
1882	265,039	4,642,125	17·51
1887	353,506	4,792,854	13·56
1891	448,379	7,166,655	15·99
1892	395,449	5,330,216	13·48
1893	379,172	4,991,300	13·16
1894	353,928	4,538,786	12·96
1895	366,120	4,239,198	11·58
	Blackplate 34,868	338,346	
1896	266,963	3,036,015	11·37
	Blackplate 48,405	477,169	

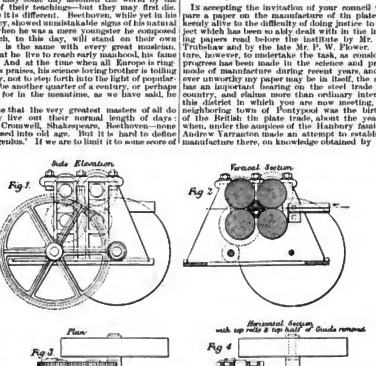
It is interesting to note in the above figures the gradually declining values of the material, and it is doubtless this which has in the past given the stimulus to the trade, and has largely added to the uses for which the material has been adapted. The largest exports were in 1891, and until that year the industry had been almost entirely confined to this country, and the American market was supplied entirely from Wales; but with the introduction of the McKinley tariff, which increased the import duty to 2·2 cents per pound (equivalent to 10s. per cwt.), works were established in the United States, and these have since been operated with considerable success. The growth of the industry there has been very rapid, the estimated output for the years ending June 30, 1892 to 1896, being as follows:

	Tons.
1892	5,903
1893	44,196
1894	62,055
1895	86,160
1896	137,053

In a report lately prepared for the British Foreign Office, it is stated that there are now 180 mills in existence in the United States, 170 of which are working, 11 new ones are in process of construction, with a total potential capacity of 6,250,000 boxes, about equal to the total American consumption in 1896, and the present production is stated to be variously estimated at from 4,000,000 to 5,000,000 boxes a year.

The imports of British tin and terne plates into the United States have rapidly declined in these years, thus:

	Tons.
1891	325,143
1893	290,546
1894	226,990
1895	221,077
1896	113,049



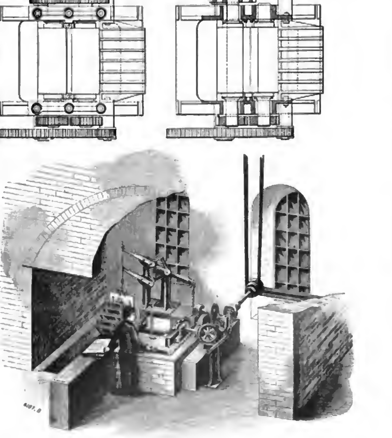


FIG. 8.

THE MANUFACTURE OF TIN PLATES.

* Paper read before the Iron and Steel Institute.

France, Germany, Italy, Spain, and Austria are also producing, and the Welsh makers are anxiously seeking markets abroad. In the meanwhile great depression exists. Of the 490 mills in Great Britain at the present time, only 302 were in operation at the end of April.

During the last fifteen years a great revolution has taken place in the trade by the general adoption of mild steel as a substitute for iron bars, which were formerly produced in the charcoal and puddling forges attached to the tin plate works of the district, with the result that these forges have been entirely abandoned and the tin plate trade proper may now be considered to commence with the rolling of the steel bar into blackplate, although some of the larger works have erected open hearth steel plants. It is my intention, however, to deal with the manufacture commencing with the steel bars.

For this purpose mills are employed, consisting of two pairs of rolls, the first pair for breaking or roughing down the steel bar into plate form, and the second for finishing the plates.

Two heating furnaces and two pairs of shears, to one of which is attached a doubling table and squeezer for doubling and flattening the sheets after elongation between the rolls. The rolls are made of a mixture of strong, tough, cold blast iron, cast in chills. Before being put to work, the necks and bodies are turned in a lathe. After being put in position in the mills the bodies are again dressed and fitted to each other, to work evenly together when expanded at their work.

I may here mention that the general practice in the United States varies by employing one pair of rolls only in a mill, the operation of roughing down and finishing being performed in the same pair, or in some cases three pairs of rolls are employed for two mills, one pair doing the roughing down for the two finishing.

The furnaces are of the reverberatory type, and the bars and sheets charged on the bed of the furnace are acted on by the flame from the grate placed at the back. Defects or wasters are sometimes produced by particles of small coal and ash being carried forward from the grate or picked up from the bed of the furnace, and subsequently rolled into the surface of the sheets. In some modern works, gas producers are employed for supplying the furnaces with fuel, and beneficial results are obtained as regards quality of plates produced and the decrease of wasters.

The workmen employed in the mills are formed in sets, consisting of a roller, doubler, furnaceman, and catcher—the roller being the head, and having charge of the mill. Three sets are employed for eight hours each in a day of twenty-four hours for five days in the week, and one set on the Saturday; the mills run continuously from Monday morning till midday on Saturday. A shearer and three openers generally cut and open the work from each mill.

The operation is as follows: The rough bars from the steel works, of suitable gage, varying from $\frac{1}{4}$ inch to $\frac{3}{8}$ inch thick and 7 inches to 10 inches in width, are cut into short lengths corresponding with the width of the plate to be produced, and are placed in the first or thick iron furnace, and when heated to redness are delivered to the roller, who passes each piece several times between the roughing rolls; the catcher, stationed behind the rolls, catches the pieces as they pass through, and returns them over the top roll. When sufficiently extended, the pieces are replaced in the same furnace, and heat equivalent to that lost in the operation of rolling is restored. When they are again extended by rolling, the doubler doubles the two ends of each piece together, flattening the piece under the squeezer, by which it should be observed the substance for resistance in the next operation of rolling is not diminished. In this stage the pieces are known as "doubles." The doubles are now charged into the second or finishing furnace, leaving the thick iron furnace free to heat another charge of rough bars while the operation of finishing the former is continued. When the "doubles" are heated the pieces are again extended, the second doubling is performed, and the uneven ends are cut off at the shears: "fours" being thus produced. The packs are again subjected to the action of the finishing furnace and prepared for final rolling, or the process is continued after further rolling and doubling to "eights," as may be necessary for the gage required. It is customary in every instance after two or more thicknesses of doubled plates have been rolled together to separate them before reheating, care being taken to replace the pieces in position in the pack; this avoids welding of the surfaces, and facilitates the final separation or opening of the finished sheets. It is known that each piece of rough bar of given weight, if carefully manipulated, will produce so many sheets of the desired size and gage, and considerable skill is required to obtain sufficient length and, at the same time, to avoid exceeding it, or the steel would cut to waste. When the roller is satisfied that he has obtained the above requirements, the pieces are placed on trolleys for conveyance to the finishing shears, and when cool are cut by the shearer into the sizes of the order in hand.

The next process is that of opening or separating the plates pressed together by the final rolling; for this girls are employed, who do the work by hand, separating sheet from sheet with much dexterity. In this state the plates are known as rough blackplate. A machine, for which a big future seems possible, has lately been invented by Messrs. Williams & White, for opening or separating blackplate or sheets, and the following description may be found of interest:

The machine consists essentially of two pairs of rolls, all driven at the same circumferential speed, and placed with their axes all parallel to each other. Between the first and second pair of rolls is placed a "waved guide," consisting of hard, smooth, chilled iron plates. These plates are firmly held at a proper distance from each other, and the "guide" formed by the two plates is firmly held in position between the two pairs of rolls, as shown in Figs. 1, 2, 3 and 4.

The action of the machine is as follows: The packs of unopened blackplate to be opened by the machine are passed through the first pair of rolls. From these they pass through the sinuous passage of the guide plates. After leaving the last bend or curve in the guide, the second pair of rolls seizes the plates and draws the packs through, completing the operation. After leaving the second pair of rolls the packs fall on a trolley, where they accumulate until wheeled away for the next process.

It may be explained that the individual sheets comprising the pack are held together by very thin films of oxide of iron, which forms on the surface during the working of the sheets while hot.

As the packs are forced around the curves of the

Fig. 5.

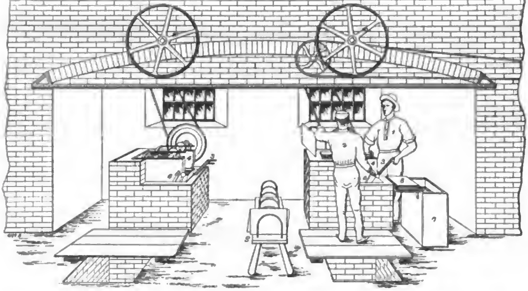

Fig 6 Section AB

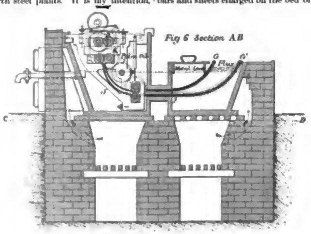

Fig 7 Plan C.D

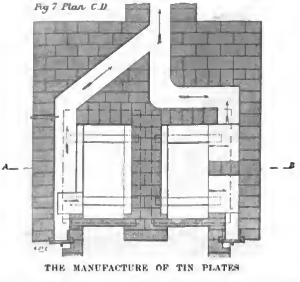

THE MANUFACTURE OF TIN PLATES

waved passage, the sheets of metal and the films of iron oxide are bent to and fro. This bending to and fro is harmless as far as the metal is concerned, but it is destructive to the films of oxide; hence the cementing medium is destroyed and the sheets are separated. The separation is further assisted by the varying velocities of the individual sheets in passing around the curves of the guides. For example, the sheet next the convex face of the guide travels slower than the sheet next the concave face. This sliding is seen by simply rolling a book with pliable covers, when the leaves step back from each other at the edges and the faces all slide on each other.

This sliding and bending is the principle upon which the machine is constructed, and the principle is the same as that of the method adopted by the girls of bending the corners of the packs when opening by hand.

One machine is capable of opening the work from four or five mills.

The average capacity of an efficient modern tin plate mill is forty to fifty boxes (of 1 cwt. each) in eight hours; but until recently, under their union rules, the workpeople have been restricted to an output of thirty-six boxes; this cannot, however, be upheld, as the only hope for this country to retain a hold on the trade is to obtain big makes and to produce cheaply. The wages paid in the mills known as the "1874 List" are as follows:

Roller, 3s. 5d. per dozen boxes = average of 10s. to 12s. per turn.

Doubler, 2s. 9d. per dozen boxes = average of 8s. to 10s. per turn.

Furnacemen, 2s. 7d. per dozen boxes = average of 7s. 6d. to 9s. 9d. per turn.

Catcher, 1s. 3d. per dozen boxes = average of 3s. 9d. to 4s. 9d. per turn.

Shearing, 1s. 1d. per dozen boxes = average of 10s. to 12s. per turn.

Openers, 6s. 3d. per 100 boxes = average of 2s. 3d. to 2s. 9d. per turn.

Black Pickling.—This operation is necessary to clean the oxide of iron formed by the action of the air on the heated surface of the plates in the mills, and is now universally done by means of machines provided with cradles, in which the plates are packed on their edges in bulk, for immersion first in diluted sulphuric or hydrochloric acid to remove the scaly oxide, and afterward in water to wash off all traces of acid; a quick, vertical, horizontal or rocking motion being conveyed to the cradles to permit the liquid to circulate through and pass between the plates under treatment. The machines most in use are those made by Mr. David Grey, of Maesteg, by the Millbrook Company, of Swansea, and by Messrs. Taylor & Struve, of Briton Ferry, the essential difference in them being the modes by which the cradles are conveyed to and from the acid and water tanks, and by which the motion is applied to the cradles in the liquids.

Great economies have been effected in labor and in the quantities of acid required by these mechanical appliances over the old fashioned hand pickling in leaden vats, the tedious process that was employed twenty years ago.

Black or First Annealing.—The plates after leaving the pickling machines are packed in piles on iron stands and are covered over with inverted iron or steel boxes, called pots, sand being used around the mouth to exclude the air. The boxes with inclosed plates are then subjected to a mild flame in a large reverberatory furnace for eight to ten hours and are then allowed to cool gradually, the object being to soften the plates that they may be more easily polished in the preparation for tinning.

Cold Rolling.—This process consists of passing the plates one by one when cold three or four times between highly polished chilled rolls working under great pressure, and is necessary to remove any buckle or unevenness from the plate and to produce a flat, bright, polished surface for receiving the coating of tin. The plates are hardened by this process, and it is necessary to give them a second or white annealing, the plates being treated in the closed pots as before, but subjected to a milder heat. On cooling they are again soft, with a bright appearance, and are in this state called finished blackplate. A second or white pickling is necessary to remove any oxide formed in the annealing processes. This process is performed in the same way as the first pickling, but the acid solution is weaker, and, after the plates are removed from the swilling tanks, they are kept in water until taken to the tin pot.

Tinning.—In former times this process was performed by soaking the plates in the molten metal and afterward arranging them on edge in a rack fixed in the grease pot to allow the surplus tin to drain off them, the thickness of the coating being determined to some extent by the length of time the plates remained in the hot grease. The process was very wasteful, and it was impossible by its means to obtain a uniform coating over the surface of the plates. About the year 1860 Mr. Edmund Morewood, of Llanelly, and Mr. John Saunders, of Corkley, invented machines with rolls placed in the grease pot to better regulate the quantity of metal, whereby an immense saving was obtained and a superior and more evenly coated plate was produced. This method, with modifications in detail, continues to the present day.

In the process as introduced by Mr. Morewood, the wet plates from the swilling troughs of the white pickling machine were immersed sheet by sheet by the tinman, twenty-five to thirty at a time, in a bath of melted palm oil to absorb the moisture on the surface of the plates and then removed and dipped into a series of pots containing molten tin at various temperatures; and, after being brushed one at a time on both surfaces by the washman with a hempen brush, they were conveyed by him to the grease pot in which the rolls revolved. The plates, on issuing from the rolls in a vertical direction, were raised by a boy and placed in a rack, from which girls removed them to dip in iron for the purpose of removing grease adhering to the surface. They were afterward polished by slightly rubbing with a duster of sheepskin or other soft material, by which the coating operation was completed.

The capacity of modern machines employed in the above method varies from thirty to forty boxes in proportion to the number of rolls working in the grease pot and the class of work in hand. The wages paid under the 1874 list are:

Tinman, 3d. per box = 7s. 6d. to 10s. per day.

Washman, 3d. per box = 7s. 6d. to 10s. per day.

Grease boy, 1d. per box = 2s. 6d. to 3s. 4d. per day.

Dippers, girls (usually two), 7s. per 100 boxes = 2s. to 2s. 9d. each per day.

Dusting, 6d. per 100 boxes = 1s. 9d. to 2s. 4d. per day.

For years past attempts have been made to economize on this method and to employ chloride of zinc as a tinning flux in substitution for palm oil in the first pot, but the results for some time were not satisfactory, and large parcels of plates coated by the experimental processes arrived at their destination in a rusty condition, owing, doubtless, to the presence of free acid in the flux and the porous nature of the iron coated; the workmen also strongly opposed the innovation, and found means to prejudice buyers and consumers against accepting delivery of any plates prepared by such methods as injurious to the food products which would be packed in them; and it was not until steel came into general use, assisted, doubtless, by the more careful preparation of the flux, that any degree of success was attained in this direction.

It is now in general use, and by its means the operation of coating is much more rapidly effected and a brighter finished plate is produced; it has also been proved beyond the possibility of doubt that the material so used is innocuous to the fish, fruit and other goods for the packing of which the plates are employed.

From this change may be dated the successful introduction of mechanical tinning pots, by which farther savings are effected in material and the services of the washman are dispensed with. These mechanical tinning pots, now known in the trade as "patents," are of various makes, the variations consisting principally in detail, each maker claiming some advantage for his machine over that of others. They may, however, be divided into two classes, in one of which the plates travel vertically and in the other in a half circular direction from the flux, through the tin and into the rolls revolving in the grease box end. Of the former type, those of Messrs. Thomas, of Melingriffith, Daniel Edwards, of Morriston, and Thomas & White, of Llangennech, and of the latter, those of Messrs. Taylor, Struve & Company, of Briton Ferry, and Player, of Clydach, are well known machines.

Fig. 5 represents a machine of the vertical type at work. This machine, patented in 1882 by Messrs. Taylor & Leyshon, and made by Messrs. Taylor, Struve & Company, of Briton Ferry, was the first single pot for coating and finishing without the aid of the washman to meet with practical success, and is still in use at many of the most important works to the present time, with very slight alteration in detail. The principle employed being that of drawing or pulling the plates, by means of a nipping appliance working beneath the surface of the metal, through the flux into the tin in a vertical direction, so as to allow the plate to clear itself of any scruff adhering to it. The plates enter and leave the pot perfectly flat, and a coating of any quality may be produced, this being regulated by the speed of the rolls in the grease box and by the quantity of tin in the troughs under the finishing rolls, which also tends to wash off any scruff taken up in the tin pot. The machine is simple in construction and is made of various dimensions to suit the sizes of plates to be dealt with. It is specially adapted also for thin plates or taggers, the thinnest of which can be coated by it.

Figs. 6 and 7 illustrate one of the "half circular" machines. The molten tin occupies the space in the lower part of the pot, the flux lying on the surface of the tin at the feeding end, where it may be confined in position by means of a rectangular box (constructed with four sides and without ends) inserted partly below the surface of the metal. The palm oil also lies on the surface of the tin, but at the delivery end, and is confined by the grease box.

The plate is inserted by the tinman between the iron bars which form the guide, G G', and passes through the flux into the molten metal and is moved onward by a light iron rod in the hand of the tinman until it reaches the revolving rolls, H, by which it is conveyed forward through the guides, J J', out of the tin and into the finishing rolls, K K', revolving in the grease. The plate issuing from the rolls in a coated state is placed by the grease boy in a rack for removal by the dipper.

Two grates are provided, that the temperature at each end of the pot may be separately controlled, a higher degree of heat being necessary at the feeding end than is desirable at the delivery or finishing end; this is further assisted by the narrow passage or neck which forms the connection between and keeps apart the two layer bodies of the metal. Plates of any length can be coated in this pot; the makers inform us they have satisfactorily coated experimentally one continuous length of plate 6 inches in width and 150 feet long.

Some of the half circular machines are constructed with two distinct chambers. By this method the plate, after passing in a half circular direction through the first bath of tin, is conducted by means of rolls over the top of the division into the second bath of metal, above the surface of which the finishing rolls are placed in the grease, the temperature of the separate baths being controlled by a fire for each.

The method of working is substantially the same in nearly all the machines, a tinman and a boy being employed to do all the work.

Fig. 8 illustrates another machine of the vertical type at work. This machine, the invention of Messrs. Rogers & Player, is unique in its operation, as dispensing with the services of the grease boy—a tinman only being employed. The machine is of the vertical type and consists of one tin pot, with a grease pot over it, with one fire for the former and a small one for the latter, by which the necessary temperatures are maintained. The finishing rolls of this grease pot are provided with troughs containing molten metal, in which the rolls revolve with the object of washing or cleaning the plate of any scruff taken up from the tin pots. As the plates issue from the finishing rolls in the ordinary way they are automatically seized and removed to the rack to be dealt with by the dipper. This machine is known in the trade as the "iron man." The amount of tin required for coating by hand or by mechanical appliances is not material. A box of I C 14 × 20 containing 112 sheets, and with a surface area of 435·5 square feet, may be coated with a good common coke finish with about two pounds of tin, a heavier coating being applied for a charcoal finish. By means of the mechanical pots, a saving is effected in the quantity of palm oil used; hemp for brushes is entirely dispensed with and a brighter plate is produced.

Dipping and Cleaning.—The plates, on issuing from the grease pots, are either dipped by hand in fine bran, meal or shudes in two operations (each surface having to be treated), or are mechanically conveyed through the material placed in two troughs in such a way that both sides of the plates may be acted upon. When any grease which remained on the surface has thus been removed, the plates are rubbed by hand, as previously described, or are passed through a nest of rolls covered with soft sheep skins, which revolve at circumferential velocities varying to each other, by which the necessary rubbing is obtained and the dust from the bran trough is removed. The operation being now complete, the plates are sorted, counted, weighed and boxed ready for dispatch from the works.—Engineering

JOHN CABOT AND THE DISCOVERY OF NEWFOUNDLAND.*

The word America has become so completely grafted on to our cosmopolitan speech that we do not, as a rule, stay to consider the rationale of the appellation. It is true that Amerigo Vespucci, a Florentine, was one of the several explorers of the great land now from his name called America. But he was only a follower of another explorer, better known and deservedly honored, Christopher Columbus, after whom a republic, Colombia, has been called. We know that Columbus landed on one of the Bahama Islands—Guanahani or San Salvador, close to the tropic of Cancer—on October 12, 1492. But this was the first voyage of Columbus. He made other voyages, successively discovering new lands. Yet we Englishmen, a nation of great explorers, navigators and seafaring men, appear altogether to have forgotten that it is to the praise of our own King Henry VII that a northern portion of America, over sixteen hundred miles from San Salvador, was discovered, and before that portion was known to Columbus.

John Cabot, a Genoese pilot, but who had been naturalized as a Venetian, came to England and settled at Bristol with his wife and family in the reign of King Henry VII. Cabot, or Cabotta, or Kabotto, as his name is variously spelt, appears in a record in the archives of Venice, under the date March 28, 1476, as having been naturalized there after the usual residence of fifteen years. He had studied cosmography and navigation, and, for those days, had been a great traveler. He had visited Arabia, and seen at Mecca caravans which came from the East bringing vast quantities of spices. He had been told by the merchants who had care of the caravans that the spices brought by them were received by them from other merchants, who in their turn had received them from the remotest countries of the East. He fully believed in the new views which had influenced Columbus as to the roundness of the earth, and was of opinion that by sailing westward he might reach the land whence the spices came.

Details of what occurred are meager; but sufficient evidence is extant to understand some of the main features of the adventure.

Cabot applied for assistance to King Henry VII, who appears to have entered very fully into his plans, as we gather from the letters patent granted by that monarch on March 5 in the eleventh year of his reign (i. e., 1496). They are as follows:

"We have given and conceded, and by these presents do give and concede for us and our heirs to our well-beloved John Cabottus, citizen of Venice, and to Ludovicus, Sebastianus and Sanctus, sons of the said John, and to the heirs and assigns of them and each of them, and their deputies, full and free authority, faculty and power of navigating to all parts, countries and seas of the east, west and north, under our banners, flags and ensigns, with five ships or vessels of what burden or quality soever, and with as many mariners or men as they will have with them in the said ships, upon their own proper costs and charges, to seek out, discover and find whatsoever islands, countries, regions or provinces, of heathens or infidels in whatever part of the world they be which before this time were unknown to all Christians."

The letters patent then proceed to license John and his sons "to fly our banners" on the new lands, and grant the right to John and his sons to possess those lands "as our vassals," they "acquiring for us the dominion, title and jurisdiction of the same." They are to be subject to the obligation "to deduct for our use" a fifth part of the whole capital cargo of every voyage on its arrival at the port of Bristol; they are to return to the port of Bristol only; they are to be free from all customs duties. All mainlands, islands, cities, towns, camps and other places by them discovered "shall not be visited by other our subjects" without the license of John and his sons, their heirs and assigns, or their deputies, on pain of the forfeiting "by such other our subjects" of their vessels and goods. Lastly, these letters direct and command "all other our loving subjects, as well by land as by sea," to be helping and assisting the said John and his sons.

Cabot accordingly set sail in a small ship called the Matthew from the port of Bristol accompanied by two or three other small ships. Hakluyt (Voyages) says that he has copied the following from Fabian's Chronicle, but it is not to be found in any extant copy of that work. The extract is as follows:

"In the 13th year of Henry VII (1497), this year the king, by means of a Venetian, who was very expert and cunning in the knowledge of the circuit of the world and islands of the same, as by a card and other demonstrations he showed himself, caused to man and victual a ship at Bristol to search for an island which he said he knew; divers merchants of London ventured in her small stocks. The Venetian was chief patron, and in the company of the said ship sailed also out of Bristol three or four small ships freighted with merchandise, coarse cloth, caps, laces, and so departed from Bristol in the beginning of May."

It is most unfortunate that no log or account written by Cabot himself has come down to us. Even his map

* Nautical Magazine.

and globe have been lost or perished; we are, therefore, obliged to content ourselves with the testimony of contemporaries. Perhaps the most interesting and fullest account is that written by the Abbé Raimondo de Soncino, envoy of the Duke of Milan at the court of Henry VII, which is so valuable but so little known that we shall transcribe it at length. The Abbé writes* from London under date December 18, 1497, to the Duke, as follows:

"Most Illustrious and Excellent My Lord: Perhaps, among your excellency's many occupations, it may not displease you to learn how his majesty here has won a part of Asia without a stroke of the sword. There is in this kingdom a Venetian fellow—Master John Cabotta by name—of a fine mind, greatly skilled in navigation, who seeing that those most serene kings, first he of Portugal, and then the one of Spain, have occupied unknown islands, determined to make a like acquisition for his majesty aforesaid. And having obtained royal grants that he should have the usufruct of all that he should discover, provided that the ownership of the same be reserved to the crown, with a small ship and eighteen persons he committed himself to fortune; and having set out from Bristol, a western port of this kingdom, and passed the western limits of Hibernia (Ireland), and then standing to the northward he began to steer eastward, leaving (after a few days) the north star on his right hand; and having wandered about considerably, at last he fell in with terra firma, where, having planted the royal banner and taken possession on behalf of this king and taken certain tokens, he returned thence. The said Master John, being foreign born and poor, would not be believed, if his comrades, who are almost all Englishmen and from Bristol, did not testify that what he says is true. This Master John has the description of the world in a chart and also in a solid globe which he has made, and he shows where he landed, and that going toward the east he passed considerably beyond the country of the Tanais.† And they say that it is a very good and temperate country, and they think that Brazil wood and silks grow there, and they affirm that that sea is covered with fishes, which are caught not only with the net, but with baskets, a stone being tied to them in order that the baskets may sink in the water. And this I heard the said Master John relate, and the aforesaid Englishmen, his comrades, say that they will bring so many fishes that this kingdom will no longer have need of Iceland, from which country there comes a very great store of fish which we call stock fish. But Master John has set his mind on something greater, for he expects to go further on toward the east (Levant), from that place already occupied, constantly hugging the shore until he shall be over against an island by him called Cipango,‡ situated in the equinoctial region, where he thinks all the spices of the world and also the precious stones originate; and he says that in former times he was at Mecca, whither spices are brought by caravans from distant countries, and that those who brought them, on being asked where the said spices grow, answered that they do not know, but that other caravans come to their homes with this merchandise from distant countries, and these again say that they are brought to them from other remote regions. And he argues thus: That if the Orientals affirmed to the Southerners that these things come from a distance from them, and so from hand to hand, presupposing the rotundity of the earth, it must be that the last ones get them at the north toward the west; and he said it in such a way that, having nothing to gain or lose by it, I too believe it. And what is more, the king here, who is wise and not lavish, likewise puts some faith in him, for since his return he has made good provision for him, as the same Master John tells me. And it is said that in the spring his majesty aforenamed will fit out some ships and will besides give him all the convicts, and they will go to that country and make a colony, by means of which they hope to establish in London a greater storehouse of spices than there is in Alexandria. And the chief men of the enterprise are of Bristol, great sailors, who, now that they know where to go, say that it is not a voyage of more than fifteen days, nor do they ever have storms after they get away from Hibernia. I have also talked with a Burgundian, a comrade of Master John's, who confirms everything and wishes to return thither, because the admiral (for so Master John already entitles himself) has given him an island, and he has given another one to a barber of his from Castiglione, of Genoa, and both of them regard themselves as counts, nor does my lord admiral esteem himself anything less than a prince. I think that with this expedition there will go several poor Italian monks who have all been promised bishoprics, and as I have become a friend of the admiral, if I wish to go thither I should get an archbishopric. But I have thought that the benefices which your excellency has in store for me are a surer thing, and, therefore, I beg that if these should fall vacant in my absence you will cause possession to be given to me, taking measures to do this rather where it is needed, in order that they may be not taken from me by others, who, because they are present, can be more diligent than I, who in this country have been brought to the pass of eating ten or twelve dishes at every meal and sitting at table three hours at a time twice a day for the sake of your excellency, to whom I humbly commend myself.

"Your excellency's very humble servant,

(Signed) "RAIMUNDUS."

"London, December 18, 1497."

The Abbé Raimondo de Soncino (the writer of the above) has made an earlier reference to this matter in a letter § which he wrote on August 24 of the same year to his government. He says:

"Also, some months ago, his Majesty sent out a Venetian, who is a very good mariner and has good skill in discovering new islands, and he has returned safe, and has found two very large fertile new islands, having likewise discovered the seven cities, 400 leagues from England, in the west passage. This next spring his Majesty means to send him with fifteen or twenty ships."

Purchas (His Pilgrimes), writing in 1625, gives another account of this voyage, but it is not to be preferred to that of the Abbé Raimondo, because Raimondo writes before the inception of the second voyage, and also is a contemporary of Cabot, and has had the account direct from him and his companions, whereas Purchas writes from second hand information and more than a century after the time, and may have confused some of the incidents of the first with those of the second voyage. Purchas says:

"In the year 1496, there was a Venetian in England called John Cabota, who having knowledge of such a new discovery as this was (referring to the discovery by Columbus of Hispaniola or of Jamaica), and perceiving by the globe that the islands before spoken of stood almost in the same latitude with his country, and much nearer to England than to Portugal or to Castile, he acquainted Henry VII, then King of England, with the same, wherewith the King was greatly pleased, and furnished him out with two ships and three hundred men, which departed and set sail in the spring of the year, and they sailed westward till they came in sight of land in 45 degrees of latitude, toward the north, and then went straight northward till they came into 60 degrees of latitude, where the day is eighteen hours long, and the night is very clear and bright. There they found the air cold, and great islands of ice, but no ground in 100 fathoms sounding; and so from thence finding the land (now called New Scotland) to turn eastward, they trended along by it, discovering all the Bay and River named Descada to see if it passed on the other side. Then they sailed back again till they came to 38 degrees toward the Equinoctial line, and from thence returned into England. There be others which say that he went as far as the Cape of Florida, which standeth in 25 degrees."

Barrett (Antiquities of Bristol, p. 172) has the following entry: "Newfoundland was found by Bristol men, June 24, 1497 (St. John's Day), in a ship called the Matthew," and this is undoubtedly correct.

Robert Fabian (who died in 1511) says that John Cabot discovered the American continent on June 24, 1497.

Thus we see that Cabot was supported not only by royal authority, but by the pecuniary resources of Bristol merchants; that he sailed in the early part of May, 1497, with three or four small ships, one of which—probably the one in which he embarked himself—was called the Matthew; that after leaving Ireland he sailed westward, and after passing over some 700 leagues discovered land on June 24 of the same year; that he planted the English banner there, and took possession of it in the name of King Henry VII of England.

What was this land? The quantity of fish, doubtless codfish, points conclusively to the truth of what Barrett asserts, that he was in the close neighborhood of Newfoundland; he probably first touched the island of Cape Breton. If he coasted three hundred miles, he would have made a voyage of the Gulf of St. Lawrence, returning home through the Straits of Belle Isle, in which event he would have hugged a very large portion of the coast of Newfoundland. The passage between the southeast point of Newfoundland and of Cape Breton Isle is still called Cabot Straits. On his return he saw two islands on the starboard, but provisions running short he did not stop to examine them. He does not appear to have seen any human beings, but he brought home some fishing tackle and tokens that the land was inhabited.

As we see from the letters of Raimondo, the Bristol merchants were fully persuaded of the possibility of colonizing the new land, and even proposed to establish a fishery on a large scale for the purpose of stock fish.

His son, Sebastian Cabot, was also a navigator,* and it has been suggested that he endeavored to stifle the work done by his father, in order to increase his own glory, and to cause the discoveries made by his father to be attributed to him. Be this as it may, we are able to glean some information concerning John Cabot, even from the son. Sebastian had a map dated 1544 (but whether made really by him, or at an earlier date by his father, is unknown). On this map a legend appears against certain land, which seems to indicate the isle of Cape Breton, and especially that part of it called Cape Percé as being the Prima tierra vista of John Cabot; and the island which John Cabot calls St. John's Isle is probably Prince Edward Island. This legend is written in Spanish, and there is a Latin translation of it, which reads as follows:

"No. 8——John Cabot, a Venetian, also Sebastian Cabot, his son, opened this land, formerly closed to us, in the year from the redemption of the world 1494,† on the 24th day of July,‡ at five o'clock in the morning, which they called the land first seen, and a certain great island opposite to it, which they called the isle of St. John, because it was opened to them on the feast of St. John. The inhabitants of this land § are clothed in the skins of animals, and use the bow in war, arrows, darts, spears, wooden clubs, and slings. The land was sterile and uncultured, and abounding with lions,‖ white bears, and very large stags, innumerable fish—viz., seals, salmon, and great soles of one yard in length, and other different kinds of fish; there is great abundance of them, and the common people call them bacallios; ¶ to them also are dark hawks like crows, eagles, partridges of dark color, and other different birds."

Hakluyt has a similar account of this legend (Voyages, folio edition of 1589), heading it:

"An extract taken out of the map of Sebastian Cabot (cut by Clement Adams) concerning his discoveries of the West Indies, which is to be seen in Her Majesty's Privy Gallery at Westminster, and in many other ancient merchants' houses."

To return to John Cabot. He proposed to return to his new found land, as has been before suggested. On this occasion he obtained new letters patent from King Henry VII, dated the 3d of February, 1498. They recite as follows:

"To all men to whom these presents shall come sending greeting. Know ye that we of our grace especial and for divers causes us moving have given and granted and by these presents give and grant to our well beloved John Kabotto (Cabot), Venetian, sufficient authority and power that he, by him, his deputy or deputies sufficient, may take at his pleasure six English ships in any port or ports or other place within our Realm of England, or obeisance thereto, and if the said ships be of the burthen of 200 tons or under, with their apparel, requisite and necessary for the safe conducts of the said ships, and them convey and lead to the Land and Isles of late found by the said John, in our name and by our commandment, paying for them and every of them, as and if we should in and for our own case pay, and not otherwise."

The letters then proceed to grant permission to the said John Cabot to take with him "such master mariners, pages, and our subjects" as are willing to go to the said land and isles; lastly, these letters command all officers, as well by land as by sea, to be succoring the said John Cabot. It is to be observed that these letters make no mention of his sons, but as a fact he took Sebastian with him. John Cabot was now a rising man. On August 10, 1497, the king had presented him with ten pounds, a substantial sum in those days, in testimony of his discovery. We find this from the Privy purse account of the king: "10th August, 1497. To him that found the new Isle £10." Further, the king granted him an annuity of twenty pounds sterling charged on the customs of Bristol. The order is as follows:

"We let you wit that we for certain considerations Us specially moving, have given and granted unto Our well beloved John Cabot of the port of Venice an annuity or annual rent of Twenty pounds sterling, to be had and paid yearly from the Feast of the Annunciation of Our Lady last past, during Our pleasure, of our Customs and subsidies coming and growing in Our Port of Bristowe, by the hands of Our Customs there for the time being at Michaelmas and Easter by even portion. Wherefore we will and charge you that under Our Great Seal ye do make hereupon Our Letters Patent in good and effectual form. Given under Our Privy Seal at Our Palace of Westminster the Thirteenth day of December, the Thirteenth Year of Our Reign (1497)."

This order is directed by the king to the chancellor, and passed the chancery on the 28th of January, 1498.

John Cabot set sail on his second voyage in the early part of 1498 (probably in the month of June) from Bristol. Very little is known of his second voyage, and, apparently, he never returned. He took Sebastian with him, and it is from the jealous Sebastian that we obtain some few tidings of John Cabot's second voyage. He sailed with three hundred men; one ship put back to Ireland in distress. Cabot steered northwest and came to a coast (probably Labrador) running to the north, which he followed to a great distance. There he found, although it was the month of July, that large bodies of ice were floating on the sea, and that it was almost continual daylight. Having failed to find a passage round this formidable headland, he sought rest and refreshment on the coast of Newfoundland (which Sebastian calls Bacallios, i. e., codfish). Thence he coasted southward, and came about the latitude of Gibraltar, or 36° north, searching for a passage to India. But, the provisions failing, the ships returned to England, whether with or without the illustrious explorer, John Cabot, is unknown. It is clear that his son Sebastian returned to Bristol, and he and his companions (for he suppresses his father's name) had landed in several places, and saw the natives and various animals. The expedition was expected to return to Bristol in September, 1498, but it evidently returned much later.

We glean something of this second voyage from a garbled statement of Sebastian, which is taken* from the sixth chapter of the Third Decade of Peter Martyr of Angleria. Martyr says:

"These North Seas have been searched by one Sebastian Cabot, a Venetian born, whom being yet but in manner an infant, his parents carried with them into England, having occasion to resort thither for trade of merchandise, as is the manner of the Venetians to leave no part of the world unsearched to obtain riches. He, therefore, furnished two ships in England at his own charges, and first with three hundred men directed his course so far toward the north pole, that even in the month of July he found monstrous heaps of ice swimming on the sea, and in manner continual daylight, yet saw he the land in that tract free from ice, which had been melted by the heat of the sun. Thus, seeing such heaps of ice before him, he was forced to turn his sails and follow the west, so, coasting still by the shore, that he was thereby brought so far into the south, by reason of the land bending so much southward, that it was there almost equal in latitude with the sea Fretum Herculeum. Having the north pole situate in manner in the same degree, he sailed likewise in this tract so far toward the west, and he had the island of Cuba on his left hand, in manner in the same degree of longitude. As he traveled by the coasts of this great land (which he named Baccalaos), he said that he found the like course of the waters toward the west, but the same to run more softly and gently than the swift waters which the Spaniards found in their navigations southward. Wherefore it is not only more like to be true, but ought also of necessity to be concluded, that between both the lands hitherto unknown there should be certain great open places whereby the waters should thus continually pass from the east unto the west, which waters I suppose to be driven about the globe of the earth by the incessant moving and impulsion of the heavens, and not to be swallowed up and cast up again by the breathing of Demogorgon, as some hath imagined, because they see the seas by increase and decrease to ebb and flow. Sebastian Cabot himself named those lands Baccalaos, because that in the seas thereabout he found so great multitudes of certain big fishes much like unto tunies (which the inhabitants call Baccalaos) that they sometimes stayed his ships. He found also the people of those regions covered with beasts' skins, yet not without the use of

* Letter found in the state archives of Milan, first published in 1865, in the Annuario Scientifico. Translated by Prof. Bennet H. Nash, of Harvard College.

† I am unable to discover what land is here intended.

‡ Probably Japan.

§ Venetian Calendar, A. D. 1202 to 1509, i, 260.

* See an article, by the late Sir Travers Twiss, in the Nautical Magazine for July and August, 1876.

† This date is wrong, and should be 1497. It is not clear what the object of Sebastian was in giving a false date, unless it be to place a greater distance between his father and him, and to make it appear that he himself was the navigator who commanded in the voyage of 1497.

‡ This should be June; it is so in the Spanish.

§ Sebastian is here speaking from his own knowledge, for it will be remembered that his father found no inhabitants, only traces of some.

‖ Lions not in the Spanish.

¶ He means the common people of Spain, not the savages of the island, as erroneously translated by Hakluyt (Voyages, folio edition of 1589). The world bacallios is the Basque for cod.

* Hakluyt (Voyages, folio edition of 1589) has copied this, from whence we have extracted it.

reason. He also said there is great plenty of bears in those regions which used to eat fish; for plunging themselves into the water where they perceive a multitude of these fishes to lie, they fasten their clawes in their scales, and so draw them to land and eat them, so (as he saith) the bears, being thus satisfied with fish, are not noisome to men. He declares, further, that in many places of these regions he saw great plenty of copper among the inhabitants. Cabot is my very friend whom I know familiarly, and delight to have him sometimes keep me company in my own house. For, being called out of England by the commandment of the Catholic King of Castile, after the death of King Henry the VII of that name, King of England, he was made one of our counsel and assistants as touching the affairs of the new Indies, looking for ships daily to be furnished for him to discover this hid secret of nature."

It is further supposed that the discoveries of John Cabot have been preserved on the map of Juan de la Cosa, a Spaniard, who, in 1500, was supplied by the Spanish embassy in London with a copy of John Cabot's map (now lost). Cosa indicates by English flags the discoveries of Cabot along the North American coast, which appear to range from 50° to 30°—south of Cape Breton to a little south of Cape Hatteras.

In 1583, Sir Humphrey Gilbert, Kt., again took formal possession of Newfoundland in the name and to the use of Queen Elizabeth; for a perpetual witness whereof, he erected on the shore a pillar, whereon the royal arms of England were supported. Several plantations were made from England by virtue of royal letters patent; among others the London plantation in 1611, the Bristol plantation in 1618, and the plantation of Sir George Calvert, Kt., in 1621.

On the 24th of this month four hundred years will have run* since the day on which John Cabot found the new world, and it is desirable that this important event should not be allowed to remain in the quasi obscurity with which it has been surrounded for so long.

We trust that these few pages will prove interesting to our countrymen, and in some small degree help to revive the fame of John Cabot and the glory of the English monarch who sent him.

SHERSTON BAKER.

* June 24, 1497, of course, was the old style, but it is sufficiently close.

The completion of the Chicago drainage canal requires the expenditure of $3,685,648 more than the $28,258,748 now provided for, according to a majority report of the finance committee of the board of trustees recently made public, says Engineering News. This additional amount brings the cost of the canal completed ready for use up to $31,444,397. A minority report of the same committee places the required sum to finish the work at $1,366,191, and with the present state of factional ill feeling in the board of trustees considerable acrimonious discussion has resulted. The majority faction has, however, accepted the minority committee report, and a bill is now being prepared to be submitted to the State Legislature of Illinois, which amends the act of 1895 so that the present tax levy of 1½ per cent. for the construction work of the canal shall continue until 1899, instead of terminating now. The passage of this amendment will, it is believed, be sufficient to provide the $3,685,000 needed to complete the work. It is also the intention of the board of trustees to present to the legislature two other bills, one giving to the board the right to use any part of the waterway of the Illinois and Michigan Canal controlled by the State, provided said waterway is left in the condition it is found in; the other, giving to the board the right to condemn water power now existing, but which later may conflict with the needs of the sanitary district.

Remedy for Caterpillars.—A simple remedy against caterpillars consists of sprinkling with lime the plants affected. The lime is harmless to the plants, but deadly to the caterpillars. Moreover, it is washed into the ground by the rain and dew, and constitutes a good fertilizer.—Wiener Gewerbe Zeitung.

READING LESSON GIVEN BY A BLIND TEACHER.

BRUSH SHOP.

A LESSON IN NATURAL HISTORY.

METHODS OF INSTRUCTING THE BLIND IN FRANCE.

THE BRAILLE SCHOOL FOR THE BLIND AT SAINT MANDÉ.

WITH the aid of the Société d'Assistance pour les Aveugles that he had founded, M. Pephau, on the first of January, 1883, opened at Maisons Alfort the Braille School, which, first transferred to No. 152 Rue de Bagnolet, in Paris, was afterward definitely installed at No. 5 Rue Mongenot, at Saint Mandé, by the General Council of the Seine, which has made a departmental institution of it.

This school supplies a want that has long been felt by the blind. The child who is admitted to it does not simply receive a very thorough primary instruction, but is developed physically by gymnastic exercises in the open air; and he learns also to like manual labor in passing an hour or so every day in a shop provided for apprentices.

But what care and what abnegation does it not require for such instruction! Of the children taken directly by their parents to Rue Mongenot, how many have been led thither only after a genuine fight of the representatives of the school with the families? It is because a blind child yields a good revenue. No one better than he can draw looks of compassion and good sized coins from passers-by. His infirmity yields receipts. There are professional contractors who exploit him to the great profit of his poor parents. If he enters the Braille School, farewell to all this; the source of an easy revenue is cut off.

Under these conditions the work of the Braille School is not only that of instruction, but, what is doubly difficult, is also disciplinary and social. Its accomplishment requires great intelligence and patience, and especially a genuine goodness of heart and much compassion for human misery. The union of such qualities in all of Mr. Pephau's fellow laborers precisely characterizes the institution created by him, and they exhibit themselves to the visitor as soon as he has crossed the threshold of the school.

See in the corner of the yard that young woman seated upon a very low bench. To her right and left are two very young children of the maternal school recently annexed to the establishment. She is teaching them the Braille alphabet. In the Braille writing, the letters are formed of a combination of dots. The children have to get used to counting the number of these dots and conjecturing the arrangement in order to learn to read. The instructress passes the child's fingers over the page of hieroglyphics with untiring patience, while she plays with the little one and amuses it until she has taught it to find its way in this maze of dots.

The touch is the sense that it is most important to render acute in the blind. This is not all sufficient, however, for hearing, smell and taste have to come to its aid. The development of these senses has to be undertaken methodically and rationally. Before forming an opinion as to the nature and bulk of an object, the blind child has been surrounded with hundreds of elements of observation, and has been taught to remark the hardness, roughness or sonorousness of an object, and then its weight, temperature and dimensions.

In order to attain sufficient precision in the recognition of the things or beings that surround him, the child must therefore devote his senses to numerous preparatory exercises. This is the task of the instructresses. It is facilitated at the Braille School by M. Baldon, the director, who, putting his experience to profit, has grouped in one series of object lessons all the exercises capable of gradually making the development of the blind child's senses as perfect as possible. The study of lines, angles, surfaces and geometrical solids permits of learning the form of bodies by comparison. By familiarizing his hands and mind with various lengths (with sticks of 5, 10, 20, 30, 40 and 50 centimeters or of 1, 2 or 3 meters) and with spaces, the child is easily taught to estimate the dimensions of objects and also distances.

Through unremitting attention, knowing that many bodies have a special sonorousness or that the sonorousness varies according to the surroundings, the child succeeds in distinguishing the size of a room that he enters and the stature and age of the person who speaks to him. The voice, in fact, does not resound in the same way in a small room as in a large one, and does not impress the ear in the same manner coming from above or below.

To the blind everything has to be the subject of observations, such as the rolling of a carriage or of a street or railway car, the sound of a bell, the noise of a waterfall, the song of birds, the cries of animals, etc. Even his feet must furnish him with useful information as to the nature of the ground upon which they tread, whether it is macadamized, paved, etc. But, before the blind child has enough confidence in himself to mingle with life in general, or to participate in such acts of the latter as are capable of interesting him, how many patient lessons, how many wise counsels, and what ingenuity in the processes of teaching!

Nothing is more interesting than the spectacle of a class at the Braille School. To appreciate it, one should see with what rapidity and general accuracy the pupils answer the questions put to them by their mistress, such as those concerning the metrical system or natural history, for example. If a measure of capacity is put into their hands, they feel of it, weigh it with the hand, endeavor to determine the material by the rugosities of the surface and the density, and thrust their hand into it in order to ascertain its depth. If, in a lesson on natural history, any sort of an animal is placed before them, such as a starfish, mole, badger, squirrel, duck, etc., they pass their hands over its body in searching for the eyes, legs, teeth, and, in a word, the distinctive characters of each class and each animal. "This is a palmipede, madam. It has a wide bill; it is a duck," answers a pupil. "Strong legs, provided with sharp claws, long teeth directed forward, teeth sharp behind. It is a carnivorous animal, madam. It is a cat." "And this one?" "That is a rodent, a squirrel."

That a blind person can succeed in identifying an animal by feeling of its body is conceivable. But how he can indicate with precision upon a map or a globe such and such a country, such and such a river or such and such a town is not so easily explainable. In order to obtain such a result in the Braille School, the ordinary maps are replaced by maps in relief on which the principal towns, represented by copper tacks, constitute so many datum points. You can revolve the globe and ask the pupil at hazard to find a city of Europe or Asia, and he will pass his fingers over the surface and locate the places for you at once. In the same way, he will go through the streets of a plan of Paris from one point to another in designating them by name and in telling you what he sees therein, for the blind person says "see" for "touch." Another and very simple method of teaching the pupils of this school the configuration of countries has been found. This consists in putting at their disposal those wooden block maps called games of patience that children who can see amuse themselves with.

The results of such instruction, which have more than once amazed pedagogues, are due in great part to the excellence of the methods and to the personnel whose duty it is to employ them.

Certain natural dispositions of the blind for study merit notice. Although the privation of sight creates an evident inferiority, it nevertheless contributes toward increasing the faculties of reflection and reasoning. The blind pupil has an advantage over the one who can see. He is not distracted, but follows his thought or the instructress's explanation and demonstration, without being diverted therefrom (as is too often the case with pupils who have their sight) by insignificant external manifestations, such as the flight of an insect or the grimace of a companion.

Such concentration of judgment gives a visible imprint to the character of the blind, and likewise serves as a motive to the intervention of their educators. The blind pupil does not care much for play. It is necessary to make him love sports. One succeeds in doing this quite easily, and the spectacle is certainly picturesque in the yard of the Braille School at the hour of recess, with the boys playing leap frog or running without coming into collision, and the girls skipping the rope or dancing.

BASKET MAKING.

Being the issue of parents upon whom poverty has left its impress, the children admitted to the Braille School are mostly of unsound constitution. Frequent gymnastic exercises, either in the yard or in an adjoining gymnasium, contribute toward the physical development of the pupils. At the age of thirteen, the latter leave the primary school for the shop. This they are already slightly acquainted with, since manual labor is included in the programme of the primary school. What will they be taught? Simple trades, but such as will nevertheless gain for them the wherewithal to live upon in independence. Some will make brushes, others will do basketwork, others will cane chairs, and others again will make pearl flowers.

The manufacture of brushes is done in the first story. Boys and girls are occupied in this in the rooms situated to the right and left of a small central shop whence, through glazed windows, the foreman and his assistants can exercise continual surveillance. It is interesting to see with what prudent skill the blind operatives use the cutting instruments, the handling of which is reputed to be dangerous even to those who possess eyesight. The same observation is applicable to the basket workers, who cut, shape and scrape the osier with assurance and without ever injuring themselves. Just as there are boys only in the basket shop, so there are girls only in that in which objects of pearl are made.

The caning shop, which is situated upon the ground floor, is mixed. It receives apprentices of both sexes. In a portion of this hall, a few of the children are employed in the manufacture of straw chairs, and here the beginners at all trades try their hands. The apprentices and operatives are the object of the same attentive care on the part of the foremen and forewomen as that with which they are surrounded in school by the instructresses. The visitor experiences a true feeling of admiration before this beehive of industry where beings that had been seemingly destined to a life of ignorance are producing the wherewithal to assure them a tranquil and proud existence in the midst of a world from which an abyss seemed to separate them.—L'Illustration.

THE DEVELOPMENT OF THE AMERICAN BLOOMING MILL.*

By RALPH CROOKER, Jr.

THE Bessemer and open hearth processes are the survivors of many attempts to produce a cheaper or better material than that produced by puddling.

When these new methods of working iron emerged from the wholly experimental stage and became accepted commercial facts, they found the iron and steel industry already in a highly developed state. The crucible steel process was then about as perfect as it is to-day; while the making of puddled iron, stimulated to the highest degree by the building of railroads—which it had made possible—had reached a point which it has since excelled but little, if any, in quality; although for some years afterward it continued to increase in quantity.

It was to the machinery prepared for the handling of these materials—crucible steel and wrought iron—that the first ingots of the new processes—at first almost exclusively Bessemer—came, to be worked into the shapes that afforded the best market for them, or which stood most in need of such improvement in quality as they offered.

In England, where the greater part of the early development of the Bessemer was done, the ingots were at once sent to the hammer, and submitted to the same treatment as the crucible steel. I am unable to find that any attempt was made to roll it direct from the ingot during the first few years of Bessemer practice; a fortunate circumstance, I think all will agree, who are familiar with the characteristics of that early steel. The product of an English Bessemer works at this time—the middle sixties—was so small—from one to two hundred tons per week—and relatively of so little importance in the large English and Continental works, that the need of machinery especially to care for it does not seem to have been felt. It was a very simple matter to add hammers as the product of the Bessemer works increased, which it did very rapidly; and this was the universal practice, persisted in until the forge department of some of the works attained tremendous proportions, one firm alone having seventy hammers in use before abandoning the system, and making little or no change except to strengthen them and increase the size from four to five, and then to seven and ten tons.

The first to undertake the improvement of this state of affairs was Mr. John Ramsbottom. He undertook to improve the hammer itself, and brought out his duplex hammer, which consisted of two hammer heads moving horizontally toward each other on rollers, the heads being actuated by a steam cylinder through links, the ingot worked upon being placed between the hammer heads, and moved in a direction at right angles with their motion.

Several of these were put in operation, but they do not

* A paper read before the regular September meeting of the Engineers' Society of Western Pennsylvania.

seem to have altogether accomplished their purpose, at least they do not seem to have suited Mr. Ramsbottom, for he shortly afterward introduced his cogging mill, which was one of several devices brought forward at about the same time by different inventors, and the only one of them, so far as I can ascertain, which was ever put in practical use.

This mill in its general features was so nearly like the later blooming mills that one wonders how he managed to miss it. It consisted of a pair of huge housings carrying a pair of arbors, to which were bolted segments of cast iron, forming grooves which went part way around the rolls. The two rolls were made to turn in unison by means of pinions keyed to their necks, and were driven, through very high gearing, by a small reversing engine. The top roll was counterbalanced by a small hydraulic cylinder in the window of the housing between the necks, an arrangement made possible by the great diameter of the rolls—over five feet—and the top roll was forced down by a wedge, driven between the top of the housing and the top box by a hydraulic cylinder, operating through a rack and pinion. The vertical movement of the top roll with this arrangement was, of course, very limited.

While Mr. Ramsbottom was busy trying to correct the faults of his duplex hammer, by building his cogging mill, others, who were using them, were wrestling with the same problem, which was forced upon them by the constantly increasing output of their Bessemer works; and the obvious method of rolling the ingots in the "top and bottom" rolls of their rail mills was tried by several, and with considerable success.

With the English rail mills it was an easy matter to do this, and it may be well here to call attention to the distinct difference in practice existing between the English and American mills of the period (1867), a difference which had come about during the preceding ten years.

Up to 1857 the mills for heavy work—those in America being nearly all rail mills—were the same in both countries, two-high and non-reversing, the piece being returned over the top roll. In this year Mr. John Fritz put in use his hanging guide, which made three-high rail mills possible, and within a few years all the American mills were made three-high.

This was not the case in England, however, where efforts were made to improve their two-high mills by reversing the motion of the rolls between passes, so as to work the piece through the rolls in both directions, the means adopted being five gears and a clutch—many kinds of which were used—and later, reversing engines.

So at the latter end of the decade between 1860 and 1870, the universal practice in America was three-high and in England reversing two-high mills.

It is not surprising, therefore, that in its first blooming mills each country should have followed the form of mill prevailing at home; but so fixed was the difference of opinion as to their respective merits that each country stuck to its own, without a waver, for the next ten years, and without, seemingly, caring to know much about the other.

When it was shown that ingots could be bloomed successfully on the "top and bottom" rolls, larger reversing mills, built especially for the purpose, quickly followed, and several were in use at the end of the decade (1860-1870), although hammering was continued in some works for many years.

America did not begin its modern steel making as soon as England and Europe, nor did it advance so rapidly for some time after it began. There were several reasons for this. We were busy with a great war, which absorbed all our energies, most of our money and many lives, costs of installation and production generally were much greater, and uncertainty and dispute as to patent rights made it hazardous to enter upon such undertakings, so it was 1864 when the first ingots were made at Wyandotte, and they, like those produced abroad at the same time, were hammered. Troy, Pennsylvania, Freedom and Cleveland, the only other producers of Bessemer steel in that decade, all used the hammer for blooming.

It was at the beginning of the decade 1870-1880, when the production of Bessemer steel ingots in America had reached 40,000 tons for the year, that the shortcomings of the hammer began to be seriously felt, and the necessity of building blooming mills forced itself upon the steel makers of this country, and the first works to put a blooming mill in operation was Troy, which rolled its first ingots in January, 1871. This mill, following the general practice of American rolling mills, was a three-high mill, being the first three-high blooming mill in the world, as well as the first blooming mill in the United States. Its top and bottom rolls were fixed, the middle roll was carried in a pair of forged steel bolsters and was moved up or down after each pass by four screws driven from the main engine shaft, by a belt, shafting and worm gearing controlled by a belt driven reversing clutch. The tables on both sides of the rolls were raised and lowered together by hydraulic power. The top of the tables was made up of loose rollers, spaced closely, and on these the two rail ingots were pushed straight for the passes and into the rolls with bars and turned with tongs.

About six months later (July 10, 1871) the Cambria Iron Company put in operation a mill designed by Mr. George Fritz, which had much the same influence on American blooming mills as his brother's earlier invention had had on American rail mills, and fixed the type of mill in almost exclusive use for the decade. This, also, was a three-high mill; but it differed from the Troy mill in having its middle roll stationary, while the top and bottom rolls were movable. The top roll was counterbalanced, and the top and bottom rolls were moved toward the middle one between passes by screws acting together; they were, therefore, only obliged to make the full travel when opening to receive the ingot for the first pass.

The important feature, however, was the tables. These raised and lowered together by hydraulic power, and the tops were composed of rollers arranged to be driven from the main engine by gearing controlled by friction clutches. Combined with this was a manipulator, which consisted of a small car beneath the table with prongs on top of it, extending up through the table rollers when the table was down; this car was moved transversely to any desired position under the table by a hydraulic cylinder, and by lowering the ingot on to the prongs it could be turned, or by pushing the prongs against the side of the ingot it could be moved from pass to pass. This mill was a notable success.

The next year (1872) the Cleveland Rolling Mill Company built a blooming mill which deserves mention as the first reversing blooming mill built in this country and also because it was the only one of its type ever constructed here. It was a clutch reversing mill, and all the auxiliaries, tables, shears and shear tables, were driven from the train engine. As at first put down, it reversed with a three-gear clutch; this was afterward changed to the five gear system. In both cases friction clutches were used, and I believe that no blooming mill has ever been built here that reversed with crab clutches. English practice largely influenced the design of this mill, and at that time the superiority of reversing engines was not established—although it surely was shortly afterward; but that friction clutches were better than crab clutches for reversing was settled. The engineering periodicals and the records of engineering societies for some five or six years, about 1870, are full of illustrations and discussions as to the relative merits of the many devices proposed to overcome the glaring faults of the crab, and are interesting history.

These three mills (Troy, Cambria and Cleveland) may be grouped as the pioneer American blooming mills; but the Fritz mill only needs further attention, the others having had no influence whatever on the design of later mills.

If the manufacture of Bessemer steel in America made slow progress in the decade 1860-1870, it quite made up for it in the first half of the next, eight large works being built on much improved plans. These were all intended for the manufacture of rails, and hardly any other outlet for their product was looked for or expected, the power of new railroad enterprises to absorb the product seeming, at the time, to be almost limitless, while the inferior quality of much of the early steel still cast a deep shadow of suspicion on its reliability for other purposes.

For blooming ingots, of the size then made for rails, it was and is still difficult to improve on the Fritz mill; the size of the ingots not requiring excessive length of tables, and the large section of the finished bloom made it possible to do the work on short rolls of comparatively small diameter.

Under these conditions it is easy to understand why nearly all of these eight works, built between 1871 and 1876, put in Fritz blooming mills, and no other kind of mill had a trial until these conditions changed.

As these mills followed each other in rapid succession, each was an attempt to improve upon its predecessors; but the improvements were entirely confined to minor details. Driving the tables by independent power succeeded various methods of driving from the main engines, operating the table rollers automatically by V friction wheels, engaging when the tables were in either the highest or lowest position, came into use and was followed by a positive drive by means of gears, lazy tongs and reversing engines; the rolls, however, continued to be movable.

The great expansion of the Bessemer steel rail business between 1871 and 1876 was followed by an equally great depression in consequence of the business panic of 1873, and during the last half of the decade very little was done in new Bessemer construction, the efforts of the steel makers being entirely directed toward economical production, and it was these efforts which led to the first departure from what had come to be distinctly recognized as the American blooming mill.

The familiar method of increasing the tonnage was the one almost universally adopted to bring about the desired result, and so successful were the managers of the converting departments in this direction that the product of vessels soon exceeded the capacity of the casting pits to handle it, planned, as they had been, for the work of some years earlier.

Faced with this state of affairs, the Cambria Iron Company, in 1878, determined on a radical departure from the prevailing pit practice, which involved the making of ingots much larger than those in common use, and to care for these they put in a mill which deserves attention, being the first blooming mill in the country reversing with engines, and unique in other respects.

When the Freedom works were built in 1868, a plate mill had been imported from England with a reversing engine, said at the time to be "the best of its class yet produced." It was this mill and engine, with blooming rolls substituted for the original plate rolls, which the Cambria Iron Company utilized to work the large ingots. It was, therefore, an English mill; but the tables, which constituted its chief title to distinction, were American, having been designed by the late Mr. Daniel N. Jones. These consisted of large rectangular frames carrying the gudgeons of loose rollers, the bodies of which rested on solid tracks. These frames, with the rollers, were moved to and from the rolls, through a short distance, by hydraulic cylinders. It will thus be seen that when the table, with the ingot resting on the rollers, was pushed by the cylinder toward the mill, the ingot, moving twice as fast, was

A LESSON IN GEOGRAPHY AT THE BRAILLE SCHOOL.

projected over the end of the table and into the rolls. With this table was combined a manipulator which was very simple and efficient. It consisted of two hydraulic cylinders; one mounted on each side of the table, but independent of it, with the piston rods extending over it and carrying heads so shaped that by forcing them against the ingot it could be turned or moved from one pass to another. A useful feature of this manipulator was that by stopping the mill with the piece in the rolls a crooked bloom could be straightened by forcing one of the heads against it, an important advantage when ingots have been unevenly heated.

The screws of this mill were operated by a small steam engine, and the top roll was counterbalanced by hydraulic pressure.

It is a singular fact in connection with this mill, with a manipulator in successful use, that none of the numerous reversing mills built were equipped with manipulators of any kind for seven years afterward.

While the blooming mills built up to this time had all been in connection with Bessemer works and with a view to rail manufacture, the open hearth process had been steadily developed since 1870, and it is to be noted that from the time when the building of Bessemer works ceased in 1875 until the phenomenal development of new undertakings following the business revival of 1879-80, the building of open hearths was about the only new work done, and the product was at first almost as exclusively devoted to plates as the Bessemer was to rails. The hard times of the last half of the decade forced the Bessemer makers to try to dispose of a part of their steel by rolling their blooms into billets on other mills; at the same time the high quality of the open hearth metal had created a considerable demand for it; but the open hearth makers labored under great disadvantages in getting their material into marketable shape, being compelled to cast small ingots and roll them on the larger bar mills. The Fritz patents had passed into the hands of an exclusive corporation, and the small size of the open hearth works, coupled with the high cost of a blooming mill, made the open hearth people hesitate before putting in so much capital to do so little work.

At last, in 1879, Shoenberger & Company put in operation a reversing blooming mill, in connection with their open hearth furnaces, which was the first to be built except at a Bessemer plant, and also the first to be devoted entirely to the general trade in blooms, billets and slabs.

In this mill the grooves in the rolls were of varying depth, the screws were worked by power from the shears engine through a Hill clutch, and the tables, made of I beam frames and cast iron rollers, were driven and reversed by the train engine direct, through belts. The rolls were driven by a pair of reversing engines which had previously been used on a gunboat, no reversing rolling mill engines having then been made in this country. This mill is of interest, as the experience gained from it was embodied in the design of the one erected at Homestead two years later, thus having a decided bearing on the development of our modern mills, and, furthermore, because on it were made the first four inch billets rolled direct on a blooming mill.

The same reasons which led to the building of the Shoenberger mill caused other open hearth makers to do the same; but so firmly fixed was the superiority of the three-high mill over the reversing mill, in most minds, that the latter received but little consideration. To use three-high mills, however, the Fritz patents must be avoided, and, with this object in view, two mills were built, one for Naylor & Company for billets, and one for the Springfield Iron Company for rail blooms. The peculiarity of these mills was the table arrangement. At the back of the rolls was a table of loose rollers, lifted directly by a jack; on the front side were ordinary hooks, which were raised and lowered by the motion of the back table, but through less distance. A fixed driven roller was placed over the back table in such a way that when the table was raised the ingot was forced against it and thus carried into the rolls.

Another mill should here be spoken of as illustrating the expedients to which steel works managers resorted when the Fritz patents could not be used and before mills reversing with engines were accepted as good practice in this country. It was put in at the Union Works at about the beginning of 1880, and was reversed by the surface friction of large wheels with very broad faces (twenty feet and eight feet in diameter, I think) which were forced in contact by means of a hydraulic cylinder and levers. This mill was afterward replaced by a modern three-high mill, and should be remembered only as taking the place of the last hammers in the business, and as being the last attempt at reversing in any other way than by engines.

With the beginning of the decade 1880-1890 came great changes in the business conditions affecting the steel industry, and these were quickly reflected in repairs, improvements and additions to existing plants and the starting of new enterprises. The tremendous business expansion which began late in 1879 continued through 1880, 1881 and 1882, and the demand for steel works products, especially rails, was unprecedented. This demand came upon works many of which, during the preceding five years, had been run with the least possible expenditure for repairs, and were now driven to the utmost capacity. This usage of machinery quickly made necessary the replacement of several of the earlier blooming mills, while some firms added complete new plants.

In these renewals and extensions the influence of the Cambria practice of large ingots is clearly shown, all the new mills being made larger and stronger, while two mills, a three high at Bethlehem, about 1881, and a reversing mill at Cambria, in 1885, following the decided tendency of the time, were made forty-eight inches in diameter. The conclusion seems to have been reached, however, that equally good results may be obtained from somewhat smaller mills, and none have since been set up of over forty inches.

With this group of new mills the three-high mill reached a fixed standard which we may call the modern three high blooming mill, the first one embodying all its characteristics having been put down at Chattanooga in 1878, and since this time no appreciable change has taken place. In these mills the rolls are all fixed, the tables are raised and lowered by a horizontal cylinder connected with L cranks and links, and the table rollers are driven by an independent reversing engine through gears carried by a lazy tongs.

How thoroughly efficient this kind of mill has proved itself for the making of rail blooms is shown by the fact that in all the new work intended for rail making, in the decade which we are now considering, all but two were of this description—one at Scranton and the other at the Cambria Works. In this latter case the necessity of making various sizes for other purposes than rails largely governed the choice, and it is of interest that this mill replaced the original Fritz mill.

Of the many new enterprises inaugurated during this period, the works erected at Homestead in 1881 by the Pittsburg Bessemer Steel Company, from the plans of Mr. James Hemphill, claim particular attention. This plant, the beginning of the great establishment now located there, was the first Bessemer works especially built to manufacture steel for other purposes than rails; it was also the first to be put in operation after the expiration of the essential Bessemer patent, and in its construction a number of patents, supposed by many to be indispensable, had to be avoided.

In designing the blooming mill the experience gained in the Shoenberger mill—alluded to earlier in this paper—was largely availed of, and several features afterward generally used in American reversing blooming mills were introduced. The mill was driven by the first American reversing engine intended for rolling mill use; the rolls were made with all the grooves of equal depth, thus permitting the adoption of straight table rollers and the making of many sizes on one pair of rolls, and the roll screws were worked by a hydraulic cylinder through a rack and multiplying gear. The tables were constructed with I beam frames and the table rollers were driven by an independent reversing engine, the ingot being handled and turned on the tables by ordinary hooks hung from above, and tongs.

This mill proved itself very efficient, and during the following years many mills of similar character were built, the building of blooming mills receiving great impetus by reason of the change of the material used in cut nails from iron to steel and by the increasing demand for Bessemer billets, which followed rapidly when once they were fairly on the market.

In these mills, about the only changes from the Homestead mill was the substitution of heavy cast iron table frames for the I beam construction, and a simplifying of the table driving gearing.

It was on one of these mills, at the Spang Steel Works in 1885, that the first manipulator after the Cambria one of 1878 was tried, and after that they came slowly into use.

Another mill which should be mentioned in connection with the new enterprises of this time is one which was put to work at Scranton for making rail blooms, in 1888. This mill, with its engine, was imported from England, and is the only complete mill ever brought from there. It was a good sample of the typical English mill of the time; very heavy and with great power. The tables consisted of loose rollers, their necks running freely on rails, and the ingots were handled on these with tongs. This table arrangement, which was never copied by American mills, was replaced some years later by a modern driven roller table. This mill seems to have had some influence in calling attention to what could be done by increasing the engine power of our mills, which was emphasized later by the work of the Sparrow's Point mill.

With the decreasing requirements for rails in this decade, and the ever-increasing demand for steel for other purposes, the three-high mill, except for replacements in rail works, received but little attention. It seemed to be accepted, as fact, that the two-high mill was best where a wide range of work was to be done. It is for this reason that a mill put down at the Otis works, at Cleveland, to combine the advantages of both systems, requires description, being the last of the modifications of the three-high mill.

In this mill the bottom roll was fixed, the top roll was counterbalanced and worked with screws in the same manner as the top roll of a two-high mill, while the middle roll was thrown up and down between passes as in a three-high plate mill; the collars being made extra wide, to support the middle roll, which rested against them when working. The Fritz tables of this mill were thirty feet long, and the only ones of that type ever fitted to a mill for general bloom and billet work.

With the beginning of the present decade practice had become so established that but one mill may be considered as particularly departing from it. This is the Sparrow's Point mill, which is the only thoroughly American reversing mill which has yet been intended exclusively for rail blooms, and is noticeable chiefly for the great power of its engines, which demonstrated the capacity of this form of mill when properly engined; and since the installation there has been a marked increase in the power provided for mills of its class.

The three-high blooming mill reached its highest development at about the time that the two-high mill began its career, and within ten years of its inception; and since that time their number has diminished rather than increased, partly because of a reduction in the number of rail-making establishments, in which field it has maintained its pre-eminence, and shows how thoroughly adapted it was to the purpose for which it was intended.

With the two-high mill it is a story of progressive development for nearly twenty years. We did not begin with this kind of mills until it had been in use abroad for many years, but we availed ourselves little of foreign experience and followed lines of our own, improving and altering our original designs.

The first table frames made of I beams were displaced by cast iron with the bearings cast on; these were followed by built up wrought-iron and cast-iron frames with separate bearings; the present table frame being a substantial cast-iron bed plate with the bearings bolted on, and in some instances water cooled.

Table rollers of cast iron with wrought axles cast in were quickly abandoned for the wrought-iron pipe roller in general use on the three-high mills; then came the steel casting with the necks cast on, and to-day the preference is divided between these and a roller made of a cast-iron body fitted with a forged axle.

The driving of the table rollers began by taking power from the main engine, which was soon changed to the use of a separate engine driving both tables together through a countershaft; and finally the countershaft has been done away with, an engine coupled directly to the line shaft being used for each table. At the same time there has been a steady improvement in the table gearing. In the earlier mills the rollers were divided into groups driven by spurs and idlers; the number of these has been gradually reduced until each separate roller is now driven by a miter gear, and there is not a single intermediate gear or countershaft of any kind in the best mills.

Manipulators, after a few trials, superseded the old-fashioned hooks and tongs, and since 1890 have been in general use. In this matter alone there seems still to be a difference of opinion, and some half dozen kinds have their advocates.

In the mill itself, we have finally widened the windows of the housings so that the rolls may be changed through them; and we now generally use hydraulic counterbalancing for the top roll—methods which have prevailed in other countries from the beginning, but which we reached rather by evolution than by imitation. For working the roll screws there has been but slight change since hydraulic power took the place of belts and engines, although electric motors are used on some mills requiring extraordinary lift to the top roll.

The early mills were driven by engines with gearing of three or four to one; these ratios have been steadily cut down until gearing has been abandoned, and the latest mills are connected directly to the crank shaft.

It seems as though the work of simplifying the two-high mill has about reached its limit, and, like the three-high mill of fifteen years ago, there is little room left for further improvement.

THE LOUITON FLOAT.

THE LOUITON FLOAT FOR SWIMMERS.

The Louiton float, which is represented in the accompanying engravings, consists of a long bag made of sheet rubber, and which, when inflated, assumes a cylindrical form with conical extremities. At each end of the float there is a long leather attachment. Each conical extremity terminates in a narrow tubulure, which is closed by a wooden plug. This float is inflated with the mouth, and quite rapidly, too; say in less than a minute. It is afterward wound about the body, as shown in the figures. The dimensions of the apparatus are as follows: Cylindrical length, 3 meters; diameter, 5 centimeters; length of the conical extremities, 5 centimeters; internal diameter at the summit, 5 centimeters; length of tubulures, 4 centimeters, and

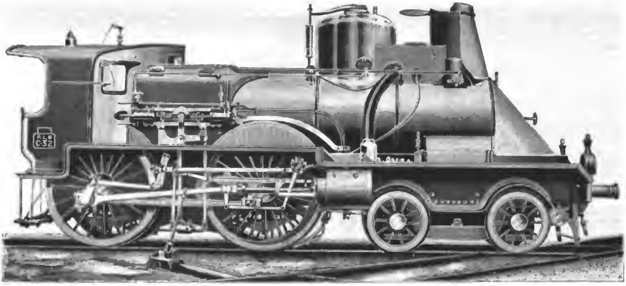
the diameter the same as that of the conical extremity. The thickness of the bag, which is uniform, is one millimeter. The total weight is exactly 520 grammes.

This float for swimming may, if need be, be made longer or shorter and have capacities of 10 and even 15 cubic decimeters. The thickness of one millimeter, although sufficient, may be doubled, if necessary. The plugs are of hard, turned wood, and taper at one extremity. In order to insert them into the tubulure, they must be wet and introduced with a screwing motion. This float is very useful. It permits any one to learn how to swim, and assures rest and safety to bathers, swimmers and others.

Experiments have shown various advantages: It is very simple, very flexible, quite strong and light, and may be easily carried, be quickly repaired and easily placed upon the body. It does not interfere with respiration, the wearing of it is attended with no inconvenience, and those who have tried it agree in the statement that it is very practical and may be recommended to swimming schools.—La Nature.

A NEW FRENCH LOCOMOTIVE.

THE remarkable contour of the locomotive we illustrate on this page needs no comment. From time to time persons forget that the end friction of elongated bodies moving at high velocities is practically negligible when compared with the side friction, and attempt to reduce resistance by providing the body with a pointed beak or prow, even at the expense of increased surface. It is true that projectiles are pointed at the leading extremity, but it has been shown by experiment that the gain in velocity from so doing is only slight. The projectile, however, flies more steadily, and it is therefore pointed. An elongated projectile with a hemispherical end, but tapering toward the rear extremity, is about as good for flight as any. The porpoise very closely follows this shape, and perhaps the great speed attained by this animal is dependent in large measure upon it. The locomotive is the first of forty constructed to the designs of M. Ch. Baudry, for the Compagnie Paris Lyons-Méditerranée. It is compound, having two low pressure and two high pressure cylinders, the latter being outside the frames, and the steam which is conducted to the chest by the exterior tubes—one of which is seen—is distributed by Walschaert's valve gear. The low pressure cylinders beneath the boilers are, for the sake of saving room and labor, provided with Gooch link motion. There are two entirely independent reversing gears. A large number of experiments has been made with several of these engines, but more with a view to testing the value of different points of cut-off in the high or low pressure cylinders than for the attainment of very high speeds, no very fast running having so far been attained with them.—The Engineer.



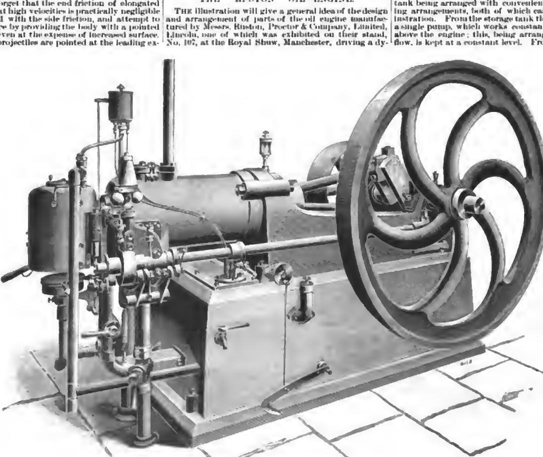
EXPRESS LOCOMOTIVE, PARIS-LYONS-MEDITERRANEAN RAILWAY.

THE "RUSTON" OIL ENGINE.

THE illustration will give a general idea of the design and arrangement of parts of the oil engine manufactured by Messrs. Ruston, Proctor & Company, Limited, Lincoln, one of which was exhibited on their stand, No. 107, at the Royal Show, Manchester, driving a dynamo and supplying the current to the "Royce" motors and machines on the adjoining stand occupied by Messrs. Royce & Company, Manchester.

There has been in the past, and there still remains, much prejudice against oil engines which ignite their charges automatically by the evolved heat of combustion, but the fault has not been in the principle of automatic ignition, but in the means which makers have adopted up to the present to produce it. In the "Ruston" engine this extremely convenient method of working is so perfectly arranged that the engine is able to run and sustain its igniting temperature equally well under all conditions of load, and has actually been run unloaded for three and a half hours under precisely the same conditions as when working with the full load. Messrs. Ruston, Proctor & Company inform us that during all the experiments, which have been very exhaustive, they have not known this engine to miss an ignition or to "back fire," as the objectionable explosion in the exhaust due to the missing fire is termed.

The engine works on the usual four-stroke cycle, and in governing cuts out such charges as are not required. By tracing the oil in its passage through the engine the working will be more clearly understood. The oil is stored in the base plate of the engine in a tank of sufficient capacity for a day's run at full power, this tank being arranged with convenient filling and drawing arrangements, both of which can be seen in the illustration. From the storage tank the oil is elevated by a single pump, which works constantly, to the cistern above the engine; this, being arranged with an overflow, is kept at a constant level. From the cistern the



RUSTON, PROCTOR & CO.'S OIL ENGINE.

petroleum is measured out in exactly equal amounts for each charge by a measuring device which can be changed, without stopping the engine, to suit different varieties of petroleum. The measuring apparatus delivers the oil charge at the right time down a tube leading to the vaporizer through the bottom of cistern.

The vaporizer itself is a spiral passage surrounded by an extension of the combustion chamber in open communication with the cylinder, the vaporizer receiving sufficient heat from the explosion within the extension of the combustion chamber to perfectly vaporize the oil charge. The petroleum is drawn through the vaporizer at atmospheric pressure, being followed and swept through the vaporizer passages by a current of air which insures the whole of each charge being delivered to the engine.

Upon the same extension of the combustion chamber, mentioned above, a simple cast iron ignition tube is placed, which, after heating up at starting, is kept at a dull red heat by the explosion within it. The ignition tube and passages surrounding the vaporizer and leading to the combustion chamber are so arranged that the products of combustion are cleared out and mixed with each incoming charge, this arrangement entirely preventing the carbon deposit which collects in the combustion chambers of so many oil engines.

The lamp is of the simplest construction, consisting of two pieces of cast iron, a dish and a cover, with an indestructible wick, by means of which the petroleum is lighted, obviating the necessity of putting in lighted waste or other makeshift, an uncleanly means of starting the lamp. A small fan, with a convenient treadle driving arrangement, feeds a blast of air to the lamp, which holds just sufficient oil to heat the vaporizer and igniter to the right temperature, and gives a number of fierce and distinct flames meeting together upon the ignition tube and vaporizer, enabling the preliminary heating to be accomplished in six or seven minutes. The engine can, therefore, be started and at work inside of ten minutes from entering the engine room.

The vaporizer and igniter are inclosed in one common cover provided with ventilating arrangements, by means of which the temperature of the vaporizer can be regulated should circumstances require it, though it is found this rarely needs adjustment, since the temperature is sufficiently sustained under all circumstances, and premature ignition is prevented by the amount of mechanical movement to be accomplished by the flame in traveling from the igniter to the main portion of the charge.

The convenience, safety and freedom from smell in having no lights which are supposed to burn constantly, but which frequently go out, either being blown out or stopped by dirt clogging up the fine holes necessary in such lamps, will be readily understood and appreciated. The vaporizer is never red hot or anything approaching it, being kept at a very moderate temperature, the igniter alone being so arranged that it approaches to a red heat.

The whole engine is extremely simple, easily started, and requires practically no attention. Where access to valves may at times be necessary or advisable metallic joints and convenient covers are arranged which can be quickly removed, so that every working part of the engine can be taken out, examined and replaced in a few minutes. As to the consumption of oil, the makers state that they have found the oil used per brake horse power per hour to be less than three-quarters of a pint of common Russian petroleum under suitable conditions and load in the medium and larger sizes, the smaller ones using a little more.

The engine can be arranged for use with any commercial petroleum of specific gravity from 0·79 and upward with very trifling changes, and the same oil is used in the lamp at starting as that burned in the engine. Messrs. Ruston, Proctor & Company are prepared to manufacture these engines in any size up to twenty brake horse power, and to supply similar engines to work with coal gas.—Engineering.

[Continued from Supplement, No. 1137, page 18169.]

PERPETUAL MOTION.—VII.*

Fig. 29 is a diagram sent us by Mr. William B. Cooper, of Philadelphia, who writes as follows in regard to it:

"Having seen in a previous issue a diagram of an attempt at perpetual motion, by H. Leonhart, I send you the inclosed diagram and description, which appears to me to correct the errors in his. The diagram represents an upright tank, through which passes a number of floats connected by a band of elastic rubber attached to their ends, leaving just enough space between them to secure action on each side by the water. They are each of the same weight as an equal bulk of water at the surface, therefore the upper one in the tank has no comparative weight. The next lower one has a unit of upward force equal to the condensation of its bulk of water, and so on, each adding a unit to the upward tendency, until we come to the last, the pressure on which is altogether downward to the amount of the entire column of water; but we already have a number of opposing upward forces, and when we look on the other side and see the thirteen active weights, it seems clear that there will be a large surplus weight, over and above the opposing weight and the friction of the rollers and upper wheel.

"Of course mercury or any other liquid could be substituted in place of water.

"If you can, by the inclosed rough diagram and description, comprehend my meaning, I would consider it a special favor if you would point out the error, if any."

The mistake of this invention is in supposing the upward pressure of the floats, added to the weight of the floats outside the tank, will more than equal the weight of a water column having a base equal to the lower side of one of the floats, and a height equal to the depth of the tank. If the floats be made of material more compressible than water, they would tend to sink rather than rise in the tank, but if made of material less compressible, the amount of upward force which could be obtained by their compression would be far less than the weight of water in the interstices between the floats. The downward effective pressure on the lower float in the tank would be the difference between this buoyancy and the weight of water in the interstices between the floats. The weight of the floats outside the tank is exactly balanced by the downward pressure of a bulk of water equal to that displaced by the floats in the tank, therefore if any motion should take place at all, it would be in an opposite direction from that expected, and would only continue till enough water had passed out of the bottom of the tank to bring the parts of the machine in exact balance.

We this week conclude our series of articles upon perpetual motion with an illustration of a machine,

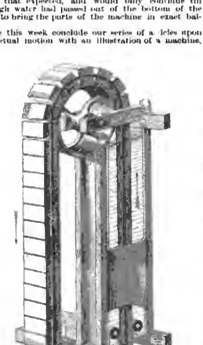


Fig. 29.

invented by a Canadian inventor, and a couple of letters upon the subject, lately received.

Fig. 30 is the device above referred to. It consists of a cylinder containing a fluid, with two or more weighted rods passing through stuffing boxes in the shell. To the middle of each of these rods is fixed a ball of cork which is expected to rise to the upper side of the cylinder whenever the revolution thereof brings it a little below the axis of the cylinder. In thus rising, it will carry the upper weight away from the center and bring the lower end toward the center, so that it is thought the center of gravity of cylinder arms, corks and metallic balls will be kept constantly on one side of a geometrical center, and constant revolution will result. The fact is, however, that the center of gravity will remain always in a perpendicular drawn through the axis, and, consequently, the expectations of the

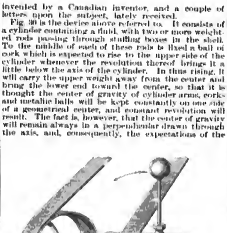

Fig. 30.

inventor will never be realized. Even if the movement of the arms expected to occur should take place when the cylinder is turned by hand, the decrease of weight on that side of the cylinder to which the cork would rise, caused by the displacement of the heavier fluid, and the increase of weight on the opposite side, caused by the displacement of the cork, would counterbalance the leverage of the weighted arms, and so the exact balance of the machine would remain undisturbed.

Messrs. Editors: This communication is especially designed for the benefit of those who still believe the perpetual motion of machinery possible. Let it be granted that the terms weight and force are synonymous, i. e., twenty pounds of weight will require a force precisely equal to the force of its own pressure to sustain it, or neutralize that pressure. For example: If a twenty pound weight be placed upon a scale, and a hand be placed upon the opposite scale, the force applied by the hand must equal twenty pounds to exactly balance the twenty pounds.

So far we only affirm what every schoolboy is aware of.

Keeping strong hold upon this self-evident fact, we may next affirm that each twenty pounds is at an equal distance from the center pin or fulcrum of the beam. Observe also this additional fact. If either weight be depressed, the opposite one will rise at the same speed and through the same distance which the other has fallen; i. e., equal weights will balance each other, at equal distances from a common point of support, and will move in opposite directions with equal velocities.

Suppose it be required that one of these weights shall rise faster than the other falls. To accomplish this, we must remove it further from the fulcrum or point of support. Observe that a scale beam corresponds to the diameter of a circle, and the arms to the opposite radii of the circle. To the unscientific, these self-evident definitions may appear puerile; but let them reflect that the grandest theorems of scientific investigation wholly depend upon a recognition of self-evident truths.

Returning again to what was proposed, viz., to cause weights at the extremities of a lever to move at unequal velocity, we find that to do so they must describe arcs of different circles, as the radii are unequal.

But in removing one weight farther from the fulcrum than its opposite we destroy the balance; for example, suppose its distance to be double that of the other, it will now move with double velocity, but will require first double weight or force at the opposite end to balance it; in other words, "all that is gained in velocity must be replaced in force at the opposite end of the beam."

The converse of this is true; i. e., we may cause a weight to raise a greater, as already shown, but if we raise forty pounds with twenty, we only raise it half the distance which the twenty pounds falls.

The above being the essence of the "law of virtual velocity," needs only to be comprehended to entirely explode all possible theories of perpetual motion.

Every attempt to produce a self-moving machine has been in open defiance to the co-ordinated relations of force and motion, and any man who comprehends this law of velocity will no sooner attempt to solve the problem of perpetual motion than to climb upon his own shoulders as a higher point of observation.

I do not propose to exhaust the numerous theories in support of the fallacy, but will analyze a few, serving as a death knell to all.

Before attempting this, let us remark that, in the search for an impossibility, so many valuable and practical certainties have been demonstrated that perhaps no time has absolutely been thrown away, for as alchemy has fostered and developed chemistry, so has the search after perpetual motion taught how to apply force through complicated machinery, and thus through unsought channels has knowledge and civilization flowed all over the world.

A favorite device of the "perpetualists" is one which proposes to employ an overshot water wheel, that shall pump or convey the water back to a reservoir as fast as it comes out. To accomplish this it only becomes necessary that all the water shall move in equal volume or weight and equal velocity in a given circle, or at opposite ends of the scale beam. A simple recognition of the principle laid down at the beginning of this article demonstrates that this is absurd.

The supporters of this species of nonsense occasionally propose to lift this water above the highest point of the circle. As this supposes the less to exceed the greater, it does not require refutation. The foregoing reasoning applies with equal force to all combinations of tubes and endless chains, belts, cups, etc., proposing finally to act upon a given circle and to be lifted back to their proper positions to continuously act upon a greater circle, or longer set of levers. These simple facts set forth, that equals can only balance equals when acting oppositely at equal distances, completely upset all possible theories of perpetual motion. But a few days since, one of this class of enthusiasts called upon the writer with a rude drawing, in which appears some half dozen geared wheels with about an equal number of mystical appearing levers, by which he exultingly proposed to propel a first class steamship across the Atlantic, by employing one man at a crank turning a geared wheel two feet in diameter. Of course, I dissented, but his faith was sublime; and he left, evidently disgusted with my shortsighted ignorance and mechanical bigotry. And so it will continue until minds of this class pause and observe a few simple and obvious truths, which, clearly recognized, make the theory of perpetual motion to fade like "the baseless fabric of a vision, leaving not a rack behind."

I. D. J. Sweet.

A humorous correspondent gives the following as a method whereby a perpetual motion may be obtained. He says he has seen a steam boiler advertised which saves 33⅓ per cent. of fuel; a valve which saves 15 per cent.; a governor which saves 10 per cent.; a cut-off which saves 10 per cent.; a fire grate which saves 20 per cent.; metal packing and damper regulator which saves 12 per cent.; and a lubricator which will save 1 per cent., making in all a saving of 101 per cent. Combining all these improvements, an engine would, he thinks, run itself, and produce an additional one per cent. of fuel, which might be used for domestic purposes.

(Conclusion.)

A motor chaise was proceeding across Ludgate Circus, London, when the driver, a young man, apparently noticing something going wrong with the car, turned it in the direction of the King Lud public house. There was then a loud explosion, which caused considerable consternation among the passers-by. The car immediately began to "run wild," but the driver preserved his presence of mind and managed to steer it against the curb. It was then discovered that the cylinder containing naphtha had burst. Fortunately, the naphtha which escaped did not ignite, and therefore an accident of a serious kind was averted.

* Reprinted from the Scientific American, 1870-71.

ENGINEERING NOTES.

A new batch of 30 knot torpedo boat destroyers is being turned over to the British Admiralty. Palmer's Chamois made 30·4 knots in the three hour trial, the highest speed on the mile course being 32·37 knots. Thornycroft's Mallard made 30·2 knots.

There was a collision on the Danish State Railroad near Copenhagen some time ago in which forty persons were killed and seventy wounded. The railroad at once admitted that it was to blame, and instead of fighting claims for damages, has appointed a committee to settle with the claimants what will be fair compensation, so as to avoid having the claims brought into the courts.

The installation of a railway line from the Caspian Sea to the Persian Gulf is at present under consideration. There are no great technical difficulties in the way of the enterprise, but it seems doubtful whether the Shah of Persia will consent to a step which will place his territory under the power of the great empire of Russia, nor can it be a pleasing prospect for England to know that Russian troops could, in case of the line being built, arrive at the Indian Ocean from Moscow within a week.—Uhland's Wochenschrift.

The only street railway in the entire province of Mozambique, Africa, is located in the town of Beira, writes United States Consul U. Stanley Hollis. This railway is about 2 miles in length, built on a 24 in. gage, and its entire rolling stock consists of one flat hand car capable of seating four people. Its motive power is from two to four stout Kaffirs. The Beira Tramway is owned by the Companhia de Moçambique, of that place. There has been some talk of a tramway at Lorenzo Marques, Delagoa Bay, but as yet nothing has been done.

Tests recently made on molybdenum steel by Prof. W. von Lipin, of St. Petersburg, show that molybdenum steel resembles tungsten steel in a general way, although it is less affected by annealing and tempering, says The Engineering and Mining Journal. Annealing makes it softer than tungsten steel; high heating, on the other hand, makes it harder than the latter. This steel can stand treatment in the fire as well as tempering better than tungsten steel, and shows no fissures where tungsten steel very often does. This may be the cause for the numerous attempts to substitute molybdenum steel for tungsten steel, and especially chromo-tungsten steel.

Lord Kelvin, in his recent address before the British Association at Toronto, gave some estimates on the available fuel supply of the world and made some suggestions which attract attention. He thinks that the utilization of water powers to the greatest extent will diminish only insignificantly the tax on the world's supply of fuel, and believes that the cultivation of vegetation which adds to the store of oxygen is of more importance than anything else man can do to prolong human life on the earth. He estimates that there exists 510,000,000 million tons of oxygen that will burn 340,000,000 million tons of fuel, but the diminution of the oxygen will destroy human life long before its supply gives out, so that the fuel that may be left after the race dies is of no avail. There are 200,000 tons of fuel for each person living to-day, which, he says, will limit the life of the race to a comparatively short span. But the growth of vegetation will be necessary to sustain life to this limit. Lord Kelvin calculates that the power now developed from the turbines at Niagara is only equivalent to the requirements of about ten ocean liners, and if the entire force of the mighty stream should be utilized, it would only be equal to the power of 100 of these ships.

The view from the Gorner Grat is considered to be the most magnificent in Europe. Monte Rosa looks close at hand, while the Matterhorn is so near that apparently one might throw a stone on it. The Gorner Grat railway, which, it is hoped, may be ready for traffic next year, will have its terminus at the summit, 10,000 ft. above the sea level, the greatest altitude yet reached on rails on that side of the Atlantic. It will start from Zermatt, where it will be connected with the branch of the Rhone Valley railway, which, in 22 miles between Visp and Zermatt, rises to the height of 8,160 ft. The new line consists of 9½ kilometers of rack and pinions, climbing the Riffel Alp to the Gorner Grat. Difficult corners are avoided by spiral tunnels having entrance and exit on the same rock face. About a mile from Zermatt it crosses a gorge by a remarkable bridge. The torrent will be utilized to furnish motive power, for the line will be on the trolley electric system. It has been only possible to carry on the construction for four and a half months in the year, and the traffic will be limited to a three months' season, as both railway and machine house will be mostly under snow for the remainder of the year. Under these circumstances the fares will be high, but people who want the luxury of a railway up a 10,000 ft. Alp must expect to pay for it.

The first light railway in England is now open. It connects Chichester with Selsey. The gage is 4 ft. 8½ in., which enables a junction to be formed between it and the London, Brighton and South Coast Railway. There are four stations on the line, but we hope they are only temporary and that the traffic will allow of the erection of more fitting examples. The canal is crossed by a drawbridge. At present the line terminates at a point about 300 yards distant from Selsey Church, but it will be advantageous to extend it before next summer for about half a mile, in order to bring visitors nearer the sea. One of the objects of the tramway is to facilitate communication with Selsey, which is likely to become a popular watering place. The success of the experiment depends in a great measure on the locomotives. The company were wise when they gave the commission for the two required to Messrs. Peckett & Sons, Atlas Locomotive Works, Bristol. The Chichester and the Selsey were specially constructed by this firm for mixed traffic, such as they are likely to have on this line. The Chichester is a six-wheeled engine (four wheels coupled) and the Selsey four wheels coupled, with a two-wheel pony truck at each end, so that the weight is distributed. In consequence, a light rail is able to be used and economy is secured. The working of the line will be watched with much interest, and it is not unlikely that from other districts orders for similar locomotives will arrive.—The Architect.

ELECTRICAL NOTES.

Brooklyn has 12,994 street gas lamps and 3,431 electric lights, says The Electrical Review. The total cost of the gas for the streets and public buildings for the year 1896 was less than $185,000, while the electric lights cost $357,698.

Germany and Spain are now connected by a submarine cable 1,250 miles long, the ends of which are at Emden and Vigo. It is the first link in a series of lines to be first extended to Brazil and to the United States by way of the Azores.

Dr. Jameson, of Transvaal fame, has taken charge of the construction of the transcontinental telegraph line across Africa from north to south. For the present it will not extend beyond Lake Tanganyika, says The Electrical Review.

An electric railway is to be run between Debreczin and Nagyvarad (Hungary), a distance of 38 miles. It will be the longest electric line of Europe. Debreczin and another town are at the same time to be supplied with electric light.—Electrotechnische Rundschau.

Prof. Crookes made the astonishing discovery that a diamond inclosed in a Crookes tube became covered with a black film. M. Moissan has investigated this film and has found it to be graphite. Further explanation is not forthcoming.—Electrotechnische Rundschau.

The electric street car line in Bernburg (Anhalt, Germany), was opened on May 1. It is the first electric tramway in the Duchy of Anhalt, and was built by the Allgemeine Electricitäts-Gesellschaft, of Berlin, Germany.—Electrotechnische Rundschau.

An experiment in the electric lighting of railway carriages is being carried out by the London and Northwestern Railway Company on its suburban line between Euston and Watford, says The Electrician. Each carriage is treated independently, having its own dynamo driven by gearing from one of the axles, and a set of accumulators to provide current when the train is not in motion. The Caledonian Railway Company is also experimenting with electrically-lit carriages on its Edinburgh-Glasgow line.

According to The London Electrical Review, an interesting process is now being conducted at Charlottenburg, Germany, by M. Mehner, by means of which ammonia and nitrides are produced. Oxygen compounds of such elements as boron, silicon, magnesium, titanium and vanadium, capable of combining with nitrogen at high temperature, are exposed to the heat of an electric furnace in the presence of free nitrogen and carbon. A high tension current must be employed and a jet of sand blown in while generator gas is introduced; on entering the hot zone of the electric furnace the sand is said to evaporate and then acts as desired. Nitrides thus manufactured may be treated with steam to obtain ammonia and an oxide from which a nitride may be reformed as before.

A novel electric elevator has been invented by H. Russell Smith, engineer of the Winslow Brothers Elevator Company, Chicago. It is stated to fully meet the exacting requirements of modern tall buildings and is styled an electromagnetic elevator, from the method of applying the power. Electrically driven elevators usually consist of steam or hydraulic elevator machinery operated by an electric motor of some variety. In this case, however, the solenoid, or coil and plunger, is used to apply the power to move a car. The inventor claims that in his form of apparatus there is far more to entitle it to the name electric than in any other style of elevator in use. An elevator built upon this principle is in successful operation in Winslow Brothers' factory.—Iron Age.

The rates of speed for street railway cars, as established by the ordinances and franchises in different cities, are as follows in and out of city limits, says The Electrical Engineer: Albany 12 miles per hour, Binghamton 12 miles, Brooklyn 6, 8 and 10 miles, Buffalo 12, 15, 18 and 20 miles, Elmira 7 and 15 miles, Rochester 6 and 12 miles, Allegheny (Pa.) 15 miles, Omaha 10 and 15 miles, Grand Rapids 7 and 15 miles, Washington 6, 12 and 15 miles, Boston 7, 10 and 12 miles, Denver 9 and 15 miles, Des Moines 8 and 12 miles, Columbus (O.) 8 and 14 miles, Dayton (O.) 10 miles, Evansville (Ind.) 12 miles, Kansas City 12 miles, Louisville 10 and 12 miles, New Haven (Conn.) 10 and 12 miles, Paterson (N. J.) 10 and 15 miles, Providence (R. I.) 9, 10 and 12 miles, Rochester 7 and 15 miles, St. Louis 10 and 12 miles.

Of the German telephone newspaper, described in these columns some time ago, The Electrical World speaks as follows, its authority being a German technical paper: "News is distributed continuously by telephone during the whole day, including some entertaining matter in the evenings, among which is always the overture at the opera house whenever there is a performance. It appears from the programme that stock quotations are given for 15 to 20 minutes about every hour or two; every few hours there is a review of the principal news items that have been transmitted before; the number of subscriptions has at present reached 6,000, including a length of wire amounting to 360 miles; it is stated that it is now possible with the apparatus in use to transmit simultaneously to 20,000 subscribers with sufficient loudness."

It is reported that a crucial test of compressed air as a possible rival of electricity has been made in a Colorado mine, says The Western Electrician. The tests extended over a month, and were made in every case under exactly similar conditions. Two small electric pumps and an air pump were placed side by side in an entry 10 ft. wide by 5 ft. high, with the exhaust of the air pump, into which a stream of water was discharged to prevent it from freezing, venting so near the electric pump that it was necessary to protect the latter from the water by an oilcloth. This was a good test for the waterproof properties of the motors. The result of the trial showed that the work of pumping by compressed air, which had formerly called for 812 horse power and eight boilers, could be done by electricity with but 56 horse power and one boiler, disregarding even the use of a compound engine and a condenser. In other words, the whole plant of pumps and machinery heretofore requiring eight boilers, taxed to their utmost, can be operated by a modern electric plant, with but one horizontal tubular boiler. The total efficiency of this electric pumping plant is estimated as close to 73 per cent.

MISCELLANEOUS NOTES.

On the Glasgow underground railroad the experiment was recently tried of doing away with tickets and letting people ride as far as they wished for a penny. On the first day of the trial, however, many persons got into the cars and spent the day riding round and round. The directors did not have the patience to wait for the novelty to wear off, but restored the ticket system after a week.

According to recent French statistics, France lost 136,000 men by death through wounds, sickness or accidents in her war with Germany, while 139,421 men were disabled on the field of battle. Germany's losses were 79,155 dead and 18,543 wounded. The monetary loss is more evenly divided, that for France being 12,666,487,522 francs, and that for Germany being 8,000,000,000 francs.

Bohemian sportsmen, during the year 1895, shot and killed 30 men, women and children and wounded 2,194 persons, chiefly gamekeepers. They also killed, among other game, over 15,000 dogs, 8,762 cats, 2 horses, 15 cows, 132 calves, 276 goats, and 129 sheep. For this they had to pay collectively over $500,000 for doctors, fines and indemnities, and to spend 74,398 days in jail. The Austrian government collects the statistics.

An apparatus, called thermophone by its inventor, is devised for finding high temperatures, and is constructed on quite a novel plan. It consists of a clay receptacle, which is filled with some explosive substance. The article whose temperature is to be measured is brought near the thermophone, and, according to the time which elapses before the explosion takes place, the temperature may be found from tables drawn up by the inventor.—Uhland's Wochenschrift.

In Germany there is no special classified duty on bicycles, the small amount paid on wheels being only that due on steel. About 1 per cent. of the value of a bicycle is paid, while in other countries the customs are from 35 to 50 per cent. The German authorities are, however, considering the levy of a special duty on bicycles imported, as the present state of things greatly tends to increase the importation of foreign goods to the detriment of home manufacturers.—Uhland's Wochenschrift.

The latest returns of the British Board of Trade show that in 87 tin plate works 272 mills were at work, as compared with 278 at the end of June and 308 at the end of July, 1896. The number of works giving full employment decreased during July from 39 (with 212 mills) to 36 (with 191 mills), while works giving partial employment increased from 16 (with 68 out of 99 mills at work) to 18 (with 81 out of 116 mills at work). The number of works entirely idle at the end of July was 33 (with 172 mills), as compared with 32 works (with 168 mills) at the end of June. The continuance of trade disputes again accounts in some measure for the stoppage of mills. Returns received from owners of 55 tin plate works show that 19,772 persons were employed at the end of July, being 365 less than at the end of June and 1,975 less than at the end of July, 1896.

The deterioration of paper is a subject of primary importance, in view of the desirability of preserving permanent records, and it is well known that the material employed for many books and periodicals is, perhaps fortunately in some cases, not of such a nature that it may be expected to survive constant handling during many years. Care ought to be exercised, therefore, in selecting paper for printed matter that may require to be frequently referred to during a prolonged period. The Council of the Society of Arts is awake to these facts, and has appointed a committee to investigate the causes of the deterioration of paper. Pharmacy is represented on this committee by Mr. Michael Carteighe, the other members being Sir Owen Tudor Burne, Sir William Anderson, Mr. C. F. Cross, Sir John Evans, Dr. Richard Garnett, Dr. Hugo Müller, Dr. W. J. Russell, Mr. W. L. Thomas, Prof. J. M. Thomson, Mr. Henry R. Tedder, Dr. Quirin Wirtz, and Sir Henry Trueman Wood. This is a goodly company, and the result of the investigations to be pursued should be of world-wide interest.

Municipal ownership of gas plants in Great Britain and Ireland is said by The London Contract Journal to prevail in 208 municipalities, while there are 437 private companies. The ownership by countries is given as follows:

	England and Wales.	Scotland.	Ireland.
Municipal	160	36	7
Private	426	2	9

The same journal gives the paid up capital of the companies as about $225,000,000, and the sums borrowed by the municipalities as about $125,000,000. The total amount of coal used is given as 11,917,440 gross tons, with an output of 121,422,000,000 cubic feet of gas, of which 111,000,000,000 was sold during the year ending March 25, 1896. The mileage of mains on the date named was 23,857, supplying 2,659,771 consumers' premises and 326,898 public lamps. The gross yearly receipts of the companies is given as about $80,000,000, and of the public plants at $30,000,000, with respective expenditures of about $45,000,000 and $20,000,000.

Terrific detonations are heard down the Schuylkill Valley on nearly every week day, from morning until night. In a secluded ravine near the Reading Railroad the Monocacy Blasting Company is breaking up big guns with dynamite. It also smashes to pieces other huge iron castings, to be sold to scrap dealers. The noise of the explosions can be heard for miles. On July 6 the company received two historic cannon, which will be broken into pieces. They were brought from the Brooklyn Navy Yard on special cars and they weigh 90,470 and 95,625 pounds. The guns were used at the Vicksburg siege by Gen. Grant's forces, firing shots of 1,200 pounds. The government officials were loath to have the guns destroyed and offered them to a number of Grand Army posts, but the necessary arrangements could not be made to have them accepted. In a few days these historic field pieces will be smashed into bits and sold for scrap. The company has broken up many defective cannon bought at gun works. It also smashes nearly all the condemned guns for the war and navy departments. The dynamite is fired by electricity and a few men do the work.

PRIMITIVE TRANSPORTATION.*

In judging the degrees or grades of culture which have characterized the different peoples of the world, the first thing to search out is some kind of a yardstick—some kind of a modulus by which those peoples can be gaged and measured. Are Philadelphians at the bottom in the industrial scale, or are they at the top or in the middle? Where are you going to place Philadelphia in the culture scale?

Lewis H. Morgan, of New York, gives in his book on

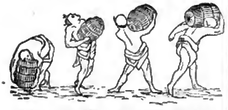

FIG. 1.—JAPANESE MAN SHOULDERING A PACKAGE OF RICE.

Ancient Society a set of gages for social measurement, viz., three grades of savagery, three of barbarism and three of civilization—nine grades altogether, based on social organization and industries. But one of the best measures of civilization is the acquisition and domestication of power for mechanical purposes.

Some tribes of men have no power under their control excepting that of the human body. Whatever they do, they do with their hands; whenever they go, they go with their feet.

In the next grade, man avails himself of the animals—the llama or others—that have become sub-

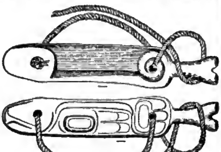

FIG. 2.—TREE-CLIMBING DEVICE OF TLINGIT INDIANS, SOUTHEASTERN ALASKA.

servient to his will, constituting beast power. Whatever be the agent—the dog, the hine, the llama, the camel, the elephant, the horse, the ass, the goat, the sheep—domesticated to come under human control, you have there an additional power added to the activities of a people. They feel the wind blowing upon their faces, see the trees bending before the gale, and the first thing you know some woman has made a mat out of grass and put it on the oar or paddle, forming mast and sail, and behold! the boat goes along through the water propelled by the wind. Or water itself may be used as a power, water floating or drifting articles

FIG. 3.—YOKAIA WOMAN CARRYING CHILD.

down stream or turning rude wheels. Man power, beast power, wind power, water power! Then add the power of fire—gross fire, fire that is more open and easy of access; after that the more refined uses of fire in steam, chemistry, electricity and light. As a result we have a series of domestications by which the peoples of the earth have conquered, one after another, these various forces of nature in order to their utilization as servants.

Looking backward, imagine a group of human beings walking upon the earth without clothing, without homes, but more particularly, without any skill. Of course they had shelter. If they wanted to go under something or into something for the purpose of keeping themselves from the rain, or the snow, or the

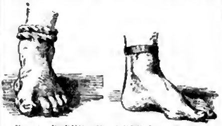

FIG. 4.—PERUVIAN ANKLE BANDS FOR TRAVELERS.

storm, or the wild beast, they had some refuge like the foxes or the moles; but they had no skill.

Mark well that epoch, that particular condition of humanity in which it was without skill; for it seems to me that the true destiny of our species is the artificial one in which we escape from the natural life and the natural proclivities and inexperiences into something that is artificial. When we multiply our wants for the sake of multiplying them, and multiply the means of gratification for the sake of multiplying our wants, we are in the stream of progress.

"Those poor wretches" (as Shakespeare calls them) "on the edge of time" had no skill, and from the skillless man of primitive time to the skillful man of Philadelphia is a long journey in many ways, in which the milestones are carrying devices, sails, windmills, engines and machines of infinite variety.

Now there are five sets of industries in which this skill in dominating power is manifested, going on from nothing to something, from absolute ignorance of things and from a want of experience in all respects to perfect knowledge, namely, exploitation, manufacture, transportation, commerce and exchange, and consumption or enjoyment.

First of all, Nature was endowed before the human period with materials that were destined to be useful to this coming race. The bounty of Mother Nature is so great that before there was a human being on the face of the earth there seemed to have been provided everything that man was going to need, if he would only look for it and find it, with this one exception; while the eagle had wings with which it could soar aloft, and the fish had fins by which it could swim, and the lion had fangs for tearing its food, and the mole

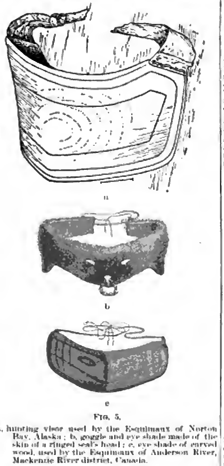

FIG. 5.

a, hunting visor used by the Esquimaux of Norton Bay, Alaska; b, goggle and eye shade made of the skin of a ringed seal's head; c, eye shade of carved wood, used by the Esquimaux of Anderson River, Mackenzie River district, Canada.

had the apparatus by which it could go underground, and each species, each family, each part of the animal creation was provided in itself, on itself, as a part of itself, with those tools and apparatuses that were going to be useful in the development of the life of those creatures, the finger nails of man will not compare with the toes of the bear; these little teeth I have in my mouth bear no comparison whatever to the teeth of the chimpanzee, or the tiger, or the lion; I have no wings with which to fly; I cannot go down into the sea very deeply, and cannot burrow in the earth like the mole. It seems to me if the animals had gathered around this weakling when first he made his appear-

FIG. 7.—THE PRIMITIVE UMBRELLA IN GUATEMALA.

ance on the earth, they would have said, "He is a poor naked wretch, indeed, and I don't believe he will stay here very long. How can he scratch for a living? how can he bite? how can he swim? He has no hair on his body; he will freeze; the hot sun will burn him up; he has no teeth by which he can grind coarse food; all of the apparatus of life seem to be so wanting in his nature; what is he going to do?" He lacked everything excepting that fertile provision of brain enlarged at the expense of bodily organs by which his thought could by and by be evoked. If he cannot bite like the lion, he can go to the volcano and there draw out the

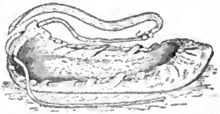

FIG. 8.—RAWHIDE SANDAL, WITH PUCKERED MARGIN, PACHACAMAC, PERU.

fire and learn how to create that fire himself so as to have in his hands a tooth that can bite sharper than that of the lion. He builds a little fire around his tent or his camping place and no lion dare go near him. The fang of the lion is very fatal, but the firebrand is more fatal. He cannot now fly into the air like the eagle, which can go only half a mile or so; but anon, you will see him soaring five, six, seven miles up into the air. The fish does not swim more than about a thousand feet down into the sea, but here comes along a creature who cannot at first even dive there; but by and by you can see him going down into the profoundest depths, and he will send machinery still further to investigate the bottom. Though he cannot

FIG. 9.—MAN'S ORNAMENTAL BOOT USED BY THE ESQUIMAUX OF POINT BARROW, ALASKA.

burrow into the ground like the mole, he will dig down one, two and three miles in the earth, bringing up the coal and iron, the gold and silver. There is nothing that any creature can do that he will not do by and by better.

Kind Nature has provided in the air, and the water and the earth the means of evoking this wonderful spirit of man; and the five sorts of industries of which I was about to speak would be, first of all, going to

* Lecture delivered at the Academy of Natural Sciences, Philadelphia, Pa., by Prof. Otis T. Mason, of the Smithsonian Institution, Washington, D. C. Revised by the author. The illustrations are from Prof. Mason's monograph "Primitive Travel and Transportation" in the Report of the United States National Museum, 1894, and are loaned by the Smithsonian Institution, cuts 8 and 10 by the Bureau of Ethnology.

Nature for her gifts, to dig up something to eat, to move into the waters or under the waters and there find something to eat, to go into the forest or field and there find something ready to eat—only simply helping himself from the bounties of Nature. Furthermore, as he will some day want to make his clothing, mats, etc., of textiles, there was plenty of textile material at hand and raw stuff for all industries.

Now, it is a curious fact that, if you look at this first

FIG. 10.—ESQUIMAU DOG HARNESSED FOR SLED.

man, this first group of human beings, these beings worthy to be called men, you will find that they are doomed to be always dissatisfied, to be driven out. Inasmuch as they have to develop themselves from within, and not on account of, or by means of, any accessories they have on the outside of them. They have to be always and everywhere dissatisfied, first of all that nothing is in the shape in which it is to be wanted.

It is said that the monkeys will take a stone and with it crack a cocoanut. The human creature is not constructed to crack a cocoanut in that way. He is first to be dissatisfied with the stone as a hammer, and to break off a piece and make some modification in the form and so become a tool maker. Whatever is, is wrong with him; that is his philosophy. It has the wrong form; he must change the form of it. As his species grows older and more skilled, he breaks the stone more and more. At last he grinds it to meal and to flour, and, last of all, he fashions therefrom his Dresden pottery, but is never satisfied with the forms of things. All the great manufactures of the world were evolutionized by this dissatisfied spirit in man.

Again, nothing is where it ought to be, even in the

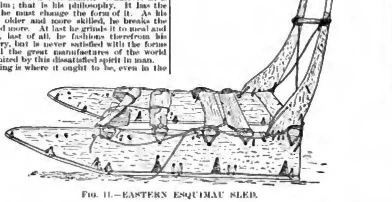

FIG. 11.—EASTERN ESQUIMAU SLED.

minds of little children. Most of the animals think that things are where they ought to be; they change the place little. But this creature that is going to dominate the earth is to be terribly dissatisfied with the places of things.

A third dissatisfaction is in the ownership of things. If there is one of these men living down on the sea that has been eating fish, and another on the hill eating nuts, the first thing you know is they are carrying their respective products one to the other for a change of diet. This swopping will lay the foundation of a whole series of industries. Forms of enjoyment are

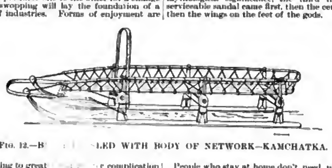

FIG. 12.—B[illegible]LED WITH BODY OF NETWORK—KAMCHATKA.

also ever changing to great[illegible]e complication of industry.

Therefore we have, first, g[illegible]fts of Nature; second, changing their for[illegible]tures; third, changing their place, or tra[illegible]and then the exchange or barter, followed[illegible]nt, consumption, using things up in their[illegible]e, constituting the fifth group.

Travel and transportation h[illegible]t forms are illustrated in your electric e[illegible]s, railway trains, chemical motors, heat[illegible]tromotors, photomotors. It was not alway[illegible] The first traveler was a barefooted human being: the first common carrier was a woman, and she had very little apparatus to do with. The first passenger car was the body, a woman carrying a child! Not a naked body carrying a naked child: apes do that. That is not where artificial carrying begins; not as the sparrow picks up a straw from the ground and flies away with it in its beak to make a nest. With that primitive man or woman who first thought of a device to carry something with, originated the beginning of transportation, the beginning of artificial travel, of artistic travel, of human travel, at that time when some sort of an instrument was invented, or used, or picked up by means of which something else was to be carried.

Much has been written of the hand, the brain and other parts of the body; but lecturers will some day discuss the human foot as a carrying apparatus. The human back, the human shoulders, the human head, the human arms, the human hand and all parts of the body, physiologically and anatomically considered, are carrying apparatus; and man is a carrying animal.

How much has the carrying trade to do with human costume? Anthropologists say dress was originally some sort of mythological or artistic ornamentation of the body, wherein the idea of clothing was an afterthought. From our point of view, dress is the first thought; its artistic form, the secondary thought; its mythological significance, the third thought. The serviceable sandal came first, then the ceremonial shoe, then the wings on the feet of the gods.

People who stay at home don't need much costume. In the Esquimau hut you will find men and women without clothing; but they never walk on foot outside in that state. The first step they take abroad they must be clad warmly. In the sunny tropics people may exist without costume, without clothing if they live in the shade; but the moment they expose themselves to the heat they have also to invent some sort of costume. Just as a house everywhere shields the family — father, mother and children — against the storm, against the sun, against the wind, against the wild beasts, so against these four factors must any costume provide that man may don to go abroad, out from under the shadow and shield of his house, in order to travel or to carry.

The first invention differentiating the travelling man is some kind of out of door costume. What is a hat? A hat is a roof—an individual roof—a covering for the head. I must have such a roof as will not cover up my face. I must see, must hear, must smell, must put all my senses at work, so that this part of my body by

FIG. 13.—PAPAGO WOMAN WITH KIBO PROPERLY MOUNTED.

which I look out upon the external world will be most exposed. If it is to be a sunny exposure, I will make an umbrella hat; if in a cold country, a fur hat; if in a snowbound land, a visor hat. Perhaps I am to walk in a country where sometimes the temperature is 80° below zero; but being an ingenious creature, I am not going to be dismayed by any cold like that; so I will go to work and invent a covering equal to that climate. If, on the other hand, I am to live where the thermometer is 120°, if there is any danger of the sun blistering my head, I am perfectly equal to inventing an umbrella or palm leaf covering. We are not afraid of anything; we are endowed to be prepared for every emergency. So this whole matter of covering the head is one of balancing between the head and the outside world. Whatever may be the climate, whatever may be the environment, the little inventor will be equal to the occasion if necessary to modify or create environments. He says this hat is very hard to carry around when the sun goes down and I no longer need the protection. Can't I devise a hat that will take down? So the parasol or umbrella is invented—

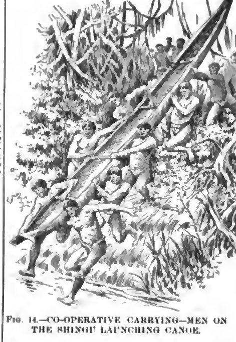

FIG. 14.—CO-OPERATIVE CARRYING—MEN ON THE SHINGU LAUNCHING CANOE.

merely a hat that will shut up—whose main cost is in preparing it to be carried. In the whole series of head coverings you have this little inventor making himself happy, as Emerson says, "in all climates and conditions," because he can cover his head.

The foot is the objective point of many traveling devices. What is the objection to going everywhere barefooted? Down in Baltimore there is a society that wander about in Druid Hill Park early in the morning, barefooted. They are perfectly welcome to their enjoyment. Our race, for a good many thousand years, have

made themselves comfortable with shoes. The human race walked over this whole earth. Before there was a beast of burden or anything tamed on which to ride, mankind had covered this whole earth. They must go on now to the end; the only problem is to be comfortable in the going. The first need was merely something to protect the foot from the ground, from wounding or the wearing out. This every one who has gone barefooted knows. You will stub your toes, or if you move into a cactus country you cannot go barefooted at all, or if into a tropical country there are many reasons why you must have something between your foot and the ground.

But, the moment you begin to travel or to carry, you are bound to look after your feet, and the sandal is the first effort to protect the foot of the traveling man from abrasions and the dangers that beset his way. No

FIG. 15.—APACHE SQUAW CARRYING CHILD.

wonder that in Grecian mythology they have Hermes with wings upon his feet. These wings are his sandals. The one invention that differentiated the traveling man from the stay-at-home was the sandal. Should any of you come to Washington, I can show you a very interesting collection of these. I have been trying to gather a sandal from every people on the face of the earth that wear sandals. Now, it is an interesting fact that in many of the inventions that have an imaginative motive behind them there is a great deal of differentiation of personal equation. If you, for example, should look at a collection of Moqui pottery, when you get the practical diameter of those vessels of a certain class, they are all between 8 and 9 inches in width; but when you read the symbols on these pots, out of 2,000 there will no two be decorated alike; when the potter came into the realm of fancy, of mythology, the individual mind just bloomed out into variation; likewise in the useful footgear there is a similarity that gives to the sandal a character of differentiation that is scientific. So when I examine the sandal of a Japanese and afterward look at another that is just like it, I say that is Japanese. No one ever saw a Chinaman wearing sandals. All the Japanese working sandals have

FIG. 16.—ESQUIMAU WOMAN OF POINT BARROW CARRYING CHILD.

the same characteristics; and these people in their daily life, in their daily arts, in their daily toil, have been brought, in some way or other, to use a certain type of shoe which characterizes their race and affiliations everywhere.

Suppose we have men on the Congo River. What do they do there? They carry, carry, carry, carry—on their heads, on their backs; year in and year out they have been going that way from the Congo down to the Gold Coast; streams of slaves going to-day just the same, and their feet are shod with shoes exactly adapted to the climate in which they are moving—just a little bunch of straw under their feet, to make a cool pad between them and the ground.

Under other conditions another kind of shoe will prevail. As you go north it is interesting to see how the sides of the sandal have been moving up over the feet—frosty nights making it necessary to get a little more covering. If you were to walk through Egypt into Palestine, into Turkestan, you would gradually convert your sandal into a shoe, and in the Siberian country into a closely made boot—the foot protected not only against abrasion from without but against the extremes of cold.

Whatever occasion may arise, you will find that as perfect music unto perfect words is this fitting or adapting of the thing used to its uses; this harmonizing of the man with his environment or surroundings goes on everywhere. Now here is a construction to be worn by a man who lives, I will say, in Alaska. It is of sealskin which has been sweated and the hair pulled out so as not to remove the thin, black cuticle. The sole has been sweated a little and the hair has been cut off carefully, leaving every bit of the cuticle. Why? Because it is a summer boot, to be worn when the snow is melting, and the foot is not only to be protected from the cold, but from the wet. That is an Esquimau waterproof boot—the upper leather tanned in the usual way. For walking over melted snow there is nothing better than that. The edge of the sole has been carried up and split; the upper leather brought down, and the seams sewed together in such a way that no water can enter.

Going around in winter the Esquimaux would have on

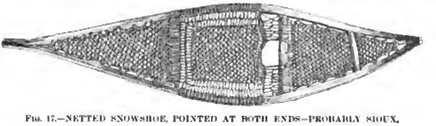

FIG. 17.—NETTED SNOWSHOE, POINTED AT BOTH ENDS—PROBABLY SIOUX.

a very different kind of a boot; but it would be exactly adapted to the conditions under which it was to be used. The same genius shown in our day in constructing electric engines is shown by these people in overcoming the difficulties which confront them. Snowshoes also form a very interesting study in this line of invention. These must have come from far North, where the snow is hard. Since the netting is coarse, the snow must have been so packed that the hunter walked on quite solid ice. In fact, the coarsest lacing either comes from the Chukchi country in northeastern Asia, or from Alaska somewhere near Behring Strait; but as you go southward you have the same story told of harmony between the ingenious mind of the individual, the inherited or tribal idiosyncrasy and the ever varying environment. The Canadian snowshoe is identified by the fineness of the mesh and the net filament. As you go farther south the snow is more liable to push up through the meshes like plastering through laths, and ball up on the snowshoe. The meshes must become smaller and smaller in order to fit them to the quality of the snow. When you reach the northern boundary of the United States, the function of the snowshoe is ended. But impelled by the irresistible spirit of progress men had to puzzle their inventive brains to improve on mere foot travel. They went to live, we will say, at some time or other, in a region surrounded by wolves—rather near to them at times—only that men had invented fire and could kindle a little circle of fire around them, outside of which the wolves howl and yelp. In the daytime these people went out of their villages and hunted the deer and the bear for food. The women cut the hides off on the outskirts of that little village, and stripped the meat from the bones. The wolves came nearer in order that they might gnaw these bones; and so a kind of treaty, or flag of truce, is sent in by the wolves. They say, "We will bark at night when there is any enemy around, and you will let us pick these bones in peace." If a mountain lion approached, these village wild beasts set up their yelping and barking, the men going out armed in order to defend themselves. If a herd of deer approached, the wolves gave notice also. Later the wolves became the scavengers of the village and the children began to tame them and lay burdens on their backs; and the men said, "You may help me carry this load;" and so the wolf becomes the domesticated dog—first a wild savage, comparative enemy, then a mutually respecting society, then a mutual admiration society; then a mutual co-operation society; and by and by comes along the period of individual ownership, and these wild, savage, bloodthirsty wolves become our domestic dogs—works of art; and we breed them just for the amusement of it.

So with the horse. He begins to find that man is more near to him than an enemy. He is hunted for food, but by and by it is found out his back is worth more than his meat; and so he is domesticated. So with the sheep and the reindeer and the camel. They have come and said, "Here we are. We will enlist in your regiment and in your service."

Animal power is now harnessed up for the use of man. Notice this, however, that in addition to the enslavement of animals, men continued to be burden bearers. The more that animals were domesticated, the more work men had to do; because their wants increased. Men toiled harder when the dog and reindeer and horse came into their service than before. The more power we get into our hands, the harder we work. I do not believe any savages that ever lived worked so hard as does a stoker in one of your comfortable steamships or a roustabout on your wharves. The more we harness up these powers—the more they are brought under our sway—the harder we have to work to enjoy them; and so it has gone on.

Now as to the use of appliances—of harness—in this work of transportation. The African in Southern Africa has a splendid head of hair, and they are not going to muss that elegant covering in carrying. So they do their transportation on their backs in great frames. The Esquimau does not carry heavy loads at all. They have a most excellent substitute for their backs in sledges or sleds. The snow is Nature's track. Long before there were any steel rails, Nature had laid all along the hyperborean region the most delightful track in the world; and these sledges placed upon these tracks go along so easily that a man can drag four times as much as he can carry on his back. The Esquimau is capable of lifting heavy loads, but he does not carry them long distances.

Coming a little further south, we find the Chilcat man—his coast is very short, his mountain very long; and across the mountains are the great Athapascan people and the mountain people who have the things that he wants; so he has to harness himself up in a way to make carrying easy. His plan is to take a strap or piece of leather and make a bandage, resting it across the forehead and putting the load upon his back. All the muscles of the head and neck are involved—part of the load resting on the shoulders, and on the back between the shoulders and on the hips; so that every carrying muscle, every part of that man's body that is capable of carrying, is involved in the operation.

Carrying with the head band and basket on the back is an American habit. It existed among the northern tribes from the earliest information we have, all down the California coast. To-day the women who do the carrying (they are the beasts of burden always and everywhere) have baskets which fit upon their backs and shoulders, and head bands across the foreheads. Mexico is the greatest land in America, and perhaps in the world, for carrying with the head band. You cannot get a photograph of anything in Mexico but some old fellow has a great big jar of water on his back; or there is a peon coming to town with a basket of meat on the back of his head, or swung from his forehead, perhaps, 200 pounds of meat—bringing them in over the hills, or over the rough passes of the mountains, competing with the railroads and underbidding them, because they have such short journeys.

Still further, in South America, you see woven into their tapestries and everywhere across the mountain sides the people with bands across the foreheads and a load upon the back. The Pueblo Indians may have possessed the head ring for toting, but the great carrying business of this continent was done on the back, with the band passing over the forehead.

In Africa, away from the Bantu country, the real negroes—the negroes of the Soudan—carry loads on their heads. Dr. Brinton's "Nations and Peoples" discusses this question among the Hamitic people of Northern Africa, but all negroes practice it as well. Carrying on the head has also prevailed all through southeastern Asia, in Phenicia, over across into the Mesopotamian Valley; in the Philippines. Down among the peoples of Polynesia toting is a very common practice, with or without harness.

When the load was transferred from the back or head of the man to the beast, of course the harness must be modified; but the main structure of the harness or strap of the man was simply taken from his body and put upon the body of the beast.

NAVIGATION OR WATER TRANSPORTATION.

Another very important link in this chain is that of navigation or traveling on the water. It is easy enough

FIG. 18.—WOMAN OF BRITTANY CARRYING CHILD.

for a man to get on a log or a bladder and float across a stream. These might not be called navigation devices at all. Navigation, or traveling and transportation on the water, as also land locomotion, would begin with some kind of an artificial device which would differentiate the boat or the ship from the mere flotation. Mere flotation, perhaps, is not navigation; yet the earliest forms of travel by water were simple flotation; but the apparatus is a manufactured one.

Going up the Mississippi or Missouri River thirty years ago you would have seen an Indian woman stretching a buffalo hide over a frame to make a very ugly looking tub. Into this tub she got with her luggage and crossed the Missouri River. In order that this craft might be steadied in its course and brought across the river, she had to invent some sort of steering gear.

The differentiation of navigation from mere floating took its rise in the invention of the keel. The simplest forms of primitive boats exhibit some effort to guide the vessel on its course, in the direction in which it does not want to go. If it tends to go this way, the human quality is to make it go that way; if the wind blows it east, the human quality compels it to go south or west. This boat is to be modified to go away from the course in which nature would take it into some other course according to the human will. This is the perfection, say, of an Esquimau woman's boat, in which the skin is drawn over a frame and the woman stands along the side and paddles it in still water.

But the man's boat, in which he is not to be afraid of any danger, in which he rights himself if capsized; puts himself down into it through a little hatch; covers himself with a waterproof jacket lashed at the bottom or lower hem around the combing; and so tightens his craft that no water can get in there, in which he faces the sea, goes out to hunt the walrus and the seal, furnishing really a first attempt to guide a craft and make a seaworthy boat. The most successful people in the world for navigation of this primitive sort are the Polynesians, who discovered every island in the Pacific Ocean 400 years before Columbus—without compass or guide of any mechanical sort, and in open boats. But they had invented three requisites to voyaging: first, to manufacture dry food—to dig a native root and grind and condense it in such a way that they could carry subsistence for a long journey; secondly they had invented a shifting sail. These poor fellows had indeed no tackle; but whenever they wished to bring the boat on the wind or off the wind they had to climb up to the masthead, untie the sail, bring it down, turn it around and put it on the other side of the mast and then sail other end first, making one end of the boat now the stern and then the bow, so that they could tack back and forth in a wind. The third epoch-making device was the outrigger. The Polynesian boat is sharp, like a very thin canoe. Across the top are timbers to which an outrigger is lashed, so that when the wind is leaning her over in one direction the sailors can climb out upon this outrigger and right her. With that craft and its outrigger and poorly shifting sails, in that little device, with their dried root and their perfectly fearless manner in the sea, the Samoans and Tongans managed to cover every archipelago in the Pacific Ocean. They went all the way from the Society Islands to the Sandwich Islands; from the Society Islands to the Easter Islands and to New Zealand; and from the Society Islands to Madagascar. From this point to the Easter Islands is over 3,000 miles.

TRANSPORTATION OF PASSENGERS—THE PASSENGER TRADE.

The first attempt to transport a human being was made by a woman in carrying her baby around in some sort of device.

In the tropics the baby does not ride in the cradle, but crawls around on the mother's back, aided by a meager girdle. How it sticks there I do not know; but whenever you examine an African picture or South American picture of native life, you will see babies crawling around on the bodies of their mothers, very little clothing on the bodies of either, and yet the youngling manages to stick there. As you go northward the little thing begins to find a refuge somewhere.

As you go farther north and the climate is colder—the temperature difference between the body of the child and the outside increases—the little fellow is gotten into some sort of a frame. In northern Mexico it is a hurdle, with a fringe or covering of deer skin; and in the cold of early morning or late in the evening this is simply thrown over the body of the child. And when the day grows warmer this curtain is thrown down. A little farther north and you will find the frame to be a trough, made of cedar; and the little one is laid in it and covered with the cedar bark. And still further north, the bed is made of fur or rabbit skins, and a little deeper it lies in this shroud or covering and it is still further protected from the climate. There is a regular harmony in this gradation. When you get to Mount St. Elias, no more cradles—too cold. The mother has a great big bonnet on her head, as large as a half bushel. The baby rests in this hood, just like the mouse in its nest; so that the carrying of a child from the tropical parts northward to the Arctic region is a tune—a kind of harmonic arrangement between the tender sympathy and care of that mother and her little helpless baby, whose life is so dear to her, and the meteorological conditions of nature.

When you cross Behring Sea into Asia you come to the same cradle you had in British Columbia—it is a wooden dugout. It can be carried on the mother's back and the child covered in and perfectly protected. But when the natives take to riding on the reindeer, or on the plains of our country begin to ride horses, and there is danger in the carrying of the child that, if it falls off it will be injured, you will find another arrangement. The Sioux Indian cradle is after this fashion, and, among all those Indian tribes where the child is exposed to injuries from falling or from wounds, there is seen a mother's provision of something to protect against the danger. The invention is always equal to the emergency. All through northern Siberia that kind of cradle is used.

The carrying of passengers on human backs becomes, in the next cultured grade above, riding on beasts. At one place they make the reindeer the "saddle horse;" in another place, the elephant; in another place, the elk; in another place, the cow, but the first beast riding is on the animal's back, with a saddle; in the next, the creature drags man over the snow in a sled or hauls him in a wheel vehicle. In Alaska, Arctic Canada and Greenland the sled is an excellent invention for the study of ethnic peculiarities co-operating with diversified surroundings. Examples from northeast Asia were brought by the Russians, who came into Alaska that way.

The north of Greenland sled is, in comparison, a poverty stricken patchwork of wreckage, held together with rawhide thongs.

The animal that draws the sled is, in every case, throughout the western world, the dog.

The origin of the wheel is a mystery, but it never could have originated in any other than a flat country. There are no roads in nature. The first roads were paths of animals, called trails; then men walked in those trails and they became paths, and after awhile became human roads, along which beasts of burden came. By and by, perhaps through some sort of a drill of these animals, in which they required more road space, the road became wider; but certainly the wheel did not originate in a hilly country. It originated in northern or western Asia, where there is a vast plain, and where all nature is one great road. To trace the four-wheel carriage of moderns through all its phases, from the original one wheel, is a long story—but it has developed in historic times.

Along this early track we travel in order that we may find the first fruits of that thinking, devising, inventing, which lie at the foundation of the most wonderful spectacle that we see to-day. We never sit down to a meal that we are not partaking of the labors of the whole earth. Our breakfasts, our dinners, our suppers, our dress that we wear, our furniture that we use—the blessings that we enjoy every day—are gathered in from the four corners of the earth, as though we could shut our eyes and hear the tramp of human feet and domesticated beasts for thousands of years over the earth, preparing the way for these great modern industries that we call transportation.

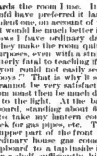
PHOTOGRAPHY AND GEOGRAPHY.

By A. E. MURRAY.

As the lantern and photography are hobbies of mine, I have much pleasure in communicating a few notes as to teaching geography by means of photography and the lime light.

First, as regards the room I use. It is about 15 feet square. I should have preferred it larger, but it was the only convenient one, on account of the windows. It faces south, but would be much better if it faced north. Over the windows I have ordinary dark green roller blinds; I find they make the room quite dark enough for teaching purposes, even with a strong sun shining. It would be utterly fatal to teaching if the room were so dark that you could not easily see your class, for "boys will be boys!" That is why it seems to me that an oil lantern cannot be very satisfactory for the purpose, as the room must then be much darker.

Secondly, as to the light. At the back of the room I have a cupboard, standing about 6 feet high, just wide enough to take my lantern comfortably, with space at the back for gas pipes, etc. The whole of one side and the upper part of the front are doors. The pipe for the ordinary house gas comes down at the back of the cupboard to a tap inside it. The lantern itself stands on a shelf, sufficiently high to clear the boys' heads. Below at the back, but inside the cupboard,



W, window; D, door; C, lantern cupboard; F, forms, S, sheet; T, teacher.

stands a box containing a 40 foot cylinder of oxygen gas. The rest of the space beneath the lantern is fitted with shelves to hold the boxes of slides, etc.

A word as to the lantern. I will not go into all its merits, for it might lead me to blow my trumpet too loudly. I will simply say that it was made for me after my own pattern. The only special point I must mention is the jet, for, after about 20 or 25 years' work with the lantern and after making several jets myself, I am convinced that for ordinary purposes, say for a disk 12 feet square, a great deal more oxygen is used than is necessary. My jet has so small an orifice that I only burn 1 foot of oxygen per hour. Also the arrangement of the nozzle of the blow-through jet is seldom, in my opinion, satisfactory. The lantern is kept always connected up with the gases, and, therefore, when the time for the class arrives, all that is necessary to be done is to put on a lime and turn the taps, and then everything is ready. In passing I may say that the cupboard is also most useful for enlarging, for, with the side door shut and the front door open for the nozzle of the lantern, it is almost dark enough; but with a piece of black twill lining fastened in front, with a round hole for the lens of the lantern, absolute darkness is obtained. A hole may be cut at the top of the cupboard to let out the heat. One more wrinkle before leaving the lantern. When I was inexperienced, if a lime broke I threw it away, but now one often lasts me for a week or more. A lime nearly always breaks in the center. Don't try to join the old breaks together if you want to use it again, but put the top and bottom ends together thus. You will find the crack will not affect the light at all, and the lime will have no tendency to break again. I far prefer the hard limes, even for

the blow-through jet, especially for semidaylight lantern work. The light is much whiter, and the hard lime withstands the dampness of the atmosphere longer. Often I leave a lime a day without putting it away, but my usual plan is to put it back into the brass tube the same night.

In front of the lantern I usually have three forms arranged as shown on the sketch. On the opposite side of the room there is a frame about eight feet square, on which a piece of white calico without a seam is stretched. Of course, if the lantern is tilted much, this ought to be slanted forward a little from the top. When teaching I usually stand about the spot, T, with a thin pointer in my hand; I need hardly say I point with the shadow, not the substance.

Now as regards the maps I use. Some I have bought, but I was so disgusted with many of those I purchased, that a year ago I determined to take up photography, chiefly for the purpose of map making and copying diagrams. Before coming to this determination I tried several of the best makers who profess to supply maps for the lantern. I will call the first firm Messrs. A. They photographed their slides from colored originals, hence some parts were very dark indeed; the maps were crowded with names. They were photographed at least twenty years ago, and the price colored I think was 3/6 each. Next came Messrs. B. Many of their maps were very good, but very expensive; I asked them to photograph one specially for me, and I supplied them with the original. When it came home it was so foggy I was ashamed to use it. A colored map I had from them is an utter disgrace to anybody, and when I complained they said it was quite true, they were very disappointed with the man who colored it, but now they had somebody far better! Another map, of Scotland (which took in a part of England), showed a large portion of Northumberland overflowed by the German Ocean. When I came to use the map for the first time I felt as much "at sea" as Northumberland must have felt. After these experiences I thought I would try Messrs. C. I wrote to them for several maps, including one of Palestine. It duly arrived, and on it all the towns, villages, etc., were duly recorded en masse, thus making it very unsuitable for a slide. I requested them to color it for me, but, alas! several of the divisions were completely miscolored! I have tried a local man, but, of course, I had to supply him with suitable maps, and I must say his photographs were as good as I could wish.

Now for my own work. Being only an infant of a year old, as may be imagined, I am not perfect yet in slide making, but I can turn out slides which are clear in the clear parts and of a good depth in the others. Personally, I like amidol best for maps; it develops very rapidly and does not seem to give the other part time to fog. Out and out the best maps I know for photography are the series published in "Outlines of Geography," by Somerville & Thompson (Percival & Company). The paper is very white and the outlines thick and black, only the important places and features are inserted. The maps themselves, here and there, are not over-correct, e. g., in the map of Europe the Apennines have disappeared from Italy, and in the map of England, Bardsey Island from off Wales, but these are trifles. Unfortunately there is no map of England divided into counties, but instead what I think almost useless, one crowded with railways. I should like to come across a series of physical maps equally suitable. To teach geography properly, there ought to be at least three maps of each country—physical, political and blank. Besides maps of countries, I also use maps showing the winds, ocean currents, etc., and I hope by and by to add geological maps. I have found it most useful to photograph the diagrams as to map making, the bed of the Atlantic, etc., given in Grove's small geography, which is the textbook for the entrance examination for the Britannia—in fact I photograph (when time permits) any picture I think suitable for the purpose, e. g., a bird's eye view of the Crimea, to illustrate a peninsula and an isthmus. But I do not confine myself to maps and diagrams. Since teaching geography by the lantern, I have been accumulating slides of different places of interest, for example, Niagara Falls, Giant's Causeway, etc., and at the end of a lesson, if the class has been attentive, I reward it by throwing on the screen two or three slides bearing, if possible, on the subject we have been taking. I consider that the results are most satisfactory, as the teacher can teach far better and the boys themselves like the plan, and I am certain they take more interest than in the ordinary way. It is also a very great advantage being able to change from one map to another so easily. The cost is decidedly not great, if you take into consideration the amount you have to pay for large school maps, and the trouble is very trifling if you have everything properly arranged and at your fingers' ends.

There is another way in which I have pressed photography into the service of geography. At the end of a term I usually want boys to fill in a map of which I give them the outline; I could not keep at hand hundreds of outlines of the different countries, so I prepare the outlines as follows: Using the lantern cupboard and the original negative, I make an enlargement on bromide paper just large enough to be copied in the cyclostyle, quarto size; I lay this enlargement on the usual thin paper of the cyclostyle and go over any lines I want to copy with a lead pencil. This makes a distinct whitish line on the cyclostyle paper. I go over this outline with the cyclostyle pen and then print off as many copies as I require. This term I used Africa, South America and Australia, prepared in this way. The enlargement will last practically for ever. No one who has not tried the plan can imagine how easy it is.

I see I have omitted all mention of coloring. Unfortunately, I cannot get time to color many of the slides, but undoubtedly it is better to do so. I have colored several in outline and find it quite sufficient. I do not think any amateur could color the whole surface of a map satisfactorily without great practice. Lastly, I may mention, although not connected with photography, that I sometimes make simple diagrams on a glass cut the size of a lantern slide, and covered with a dark orange preparation. Those I used came from Newcastle. The diagram is drawn in pencil and then gone over with the point of a needle; this produces very effective slides, the lines being bright on a dark background.—Practical Photographer.

JAPAN AND THE UNITED STATES TARIFF.

IT is quite evident that Japan means to make her influence felt in the world whenever and wherever she legitimately can. Some time ago she let the United States of America know that she had interests in Hawaii which are not to be lightly put aside, and, indeed, wherever Japan's interests are affected, there she has agents who intelligently and clearly do all in their power to safeguard them.

The United States tariff has lately been receiving the

great attention of the Japanese Chamber of Commerce, and memorials and representations have been made to the United States government and to the American Chamber of Commerce, pointing out the disastrous effects which the proposed tariff would have on the trade between the two countries. These representations do not seem to have had much effect, as the tariff bill has passed with a few modifications; still, as indicating the opinions of intelligent and influential Japanese on the question, it will be interesting to note the action which has been taken in the matter by the Yokohama and Tokyo Japanese Chamber of Commerce. The chairman of the Tokyo Chamber of Commerce telegraphed to the chairman of the United States Senate Committee on Foreign Relations, to the effect that if the tariff bill were carried out, it would ruin the trade between the United States and Japan, and, therefore, the Tokyo Chamber of Commerce requested the committee to give the matter its most serious consideration. The Yokohama Chamber of Commerce, in its memorial, pointed out that the United States of America occupied not only a most prominent position among the countries with which Japan was commercially connected, but also that it had close relations with Japan in other respects. The recent expansion of the Japanese maritime service had so considerably increased the facilities of communication between the two countries that the opportunity presented itself for the furtherance of mutual commerce. Under these circumstances it was absolutely indispensable that both nations should take such steps as were calculated to enlarge their commercial relations, to consolidate their friendly feelings toward each other and to promote mutual interests. If the proposed tariff were put into effect, it would have a disastrous effect on the trade, and be sure to impair the commercial peace existing between the two countries. The comparatively high taxes contemplated by the new tariff are to be imposed upon silk manufactures, tea, carpets, fancy matting, and earthen and porcelain wares, all of which constitute staple articles of production in Japan. The memorial admitted that the trade between Japan and the United States in past years had been rather one sided. The United States had proved excellent customers for Japanese raw silk, silk manufactures, tea, etc., while Japan had only bought kerosene oil, flour and a few other commodities. But recently there had been wider developments, and locomotives and machines, cotton, velvets, hardware and many other articles formerly imported from various countries of Europe had recently been purchased from America. Thus commerce with America had been advancing in proper sequence of progress, with every prospect of a brighter future, and it never entered the imagination of Japanese business men that such a tariff would be presented to a legislature which, to a certain extent, had always exhibited toward Japan a warm sentiment of sympathy. The memorial from the Tokyo Chamber of Commerce was in very similar terms. Indeed, it went so far as to say that the proposed tariff could not but give rise to a suspicion that the object of the projected tariff revision was especially to prohibit the importation of Japanese manufactured goods. Bearing in mind that Japan had always felt a lively gratitude for the good will shown by America, the memorialists were at a loss to perceive what had induced her to take this sudden action. While admitting that the balance of trade had always been against America, the memorialists said that so great has been the Japanese desire to show their good will to that country, that they had sincerely endeavored to maintain a balance of trade between the two countries by giving large orders for rails and warships. This is a confession which ought to be noted by British steel manufacturers and shipbuilders. The memorialists stated that when they found, notwithstanding these expressions of good will on the part of Japan, that America actually proposed to prohibit the importation of Japanese manufactured goods, the whole nation could not but be astonished at such unexpected action, which would not only seriously injure their national feelings, but also be prejudicial to the trade between the two countries.—London Engineering.

THE GLOW WORM AND THE X RAYS.

Several Coleoptera of the tribe Lampyridæ possess the property of emitting light, but the name of glow worm is reserved especially for one of the most widely distributed species, the Lampyris noctiluca (Fig. 1). This is an insect belonging to the order Coleoptera, tribe Malacoderma, and family Lampyrids. The light of the male is scarcely visible. It is the female only that, properly speaking, is the glow worm. The larvæ also are called by this name, but they are always less luminous than the females. The photogenic apparatus (Fig. 2) occupies the underside of the three last rings of the abdomen in the female, and of the two last in the male, in which it is but slightly developed. The larvæ, which are alike in both sexes, feed especially upon terrestial mollusks. They pass the winter in a torpid state. At the moment of pupation, their skin splits upon the sides of the thorax, and not upon the back, as happens with other Coleoptera.

The chrysalis of the male is immovable, as in all the insects of this order, but by a singular exception that of the female is agile and phosphorescent like the larva and the adult (or perfect) female. The eggs likewise are phosphorescent. The adults begin to make their appearance at the end of May. The phosphorescence lasts for two or three days after death (to a slight degree), and Macaire (Annales de Physique et de Chimie) has shown that it may be rendered sensible by heating the insect.

This magic gift has long rendered this insect as celebrated among children as in the world of naturalists.

Without going back to Pliny or to the encyclopedists of the middle ages, several scientists of our century have studied its curious luminosity; and among others, Macartney (1810) and Matteucci (1846), who have thrown much light upon certain points. In 1880, the question was taken up by M. Jousset. According to his researches, the granular protoplasmic cells produce a substance that becomes luminous in contact with the air introduced by the tracheæ, and the phosphorescence of the lampyris is a general property of the protoplasm, proceeding from a disengagement of phosphureted hydrogen.

These conclusions do not seem to accord with the researches recently made by Prof. Muraoka, of the University of Kioto. Let us give these latter a moment of our attention. M. Becquerel, having found that certain fluorescent substances, such as the salts of uranium, emit rays analogous to those of Roentgen, the Japanese physicist conceived the idea of examining, from this view point, the light of the lampyris; and following are the principal results obtained in the course of his investigations, an account of which is given in the Annalen der Physick und Chemie.

In a preliminary experiment, this scientist placed thin plates of copper, aluminum and brass alongside of each other upon a photographic plate. In order to prevent a contact of the plate with the metals, he interposed a sheet of cardboard provided with a circular

Fig. 1.—GLOW WORM.

aperture in the centre. The whole, placed upon the bottom of a flat box, was covered with several thicknesses of black paper. He placed upon this about three hundred glow worms, which, along about the middle of June, are met with in abundance in the environs of Kioto, and hunting for which is one of the favorite pastimes of the gentle sex in the empire of the Mikado (Fig. 3). A net prevented them from flying away during the two days in which they were held as prisoners, and the apparatus was arranged in a dark room, to prevent the effect of extraneous light.

The question was to ascertain whether the rays emitted by the worms and filtered by the paper were capable of passing through the metals, and then of acting upon a photographic plate. The circular apertures formed in the sheets of cardboard permitted of the estimation, by comparison, of the intensity of the action. It was remarked that the parts of the plate in contact with the sheets were blackened, while the places corresponding to the apertures were unaltered.

But was the photographic impression due solely to the simple contact of the cardboard? In order to solve this question, Prof. Muraoka repeated the experiment in suppressing the metals and in leaving only the sheets of cardboard provided with a circular aperture. Upon development, the part corresponding to this aperture was black, and the parts in contact did not appear to be so dark. The juxtaposition of the cardboard and the photographic plate was therefore not the sole cause of the phenomena observed.

On another hand, upon reversing the order of the experiment, that is to say, upon placing the plates of metal directly upon the photographic plate, and the sheets of cardboard on top, the places opposite the apertures underwent no alteration, while the rest was uniformly colored. Nothing occurred, however, when there was arranged upon a plate of copper provided with an aperture a sheet of non-perforated cardboard. Besides, aluminum was more easily traversed than copper, and the latter still more easily than tin. As for the thickness, that did not seem to play much of a part. The same was the case with the color of glass, which had no influence whatever upon the transmission of light, and contrary to what occurs with the Roentgen rays, the substances that cause fluorescence were permeable to the light of the glow worm. Yet there was, as with the X rays, a certain relation between the permeability and density. Finally, the phenomena manifested themselves only when the sheet of perforated cardboard was placed either in direct contact with the photographic plate or beneath a plate of metal or cardboard that filtered for a second time the rays that had already passed through black paper. Upon increasing the number of the sheets of perforated cardboard (these being superposed one above the other), the intensity of the photographic impression was correspondingly increased.

From all these experiments, as well as from others that are not so important (for which we refer the reader to the original memoir), we have the right to conclude that the light of the glow worm depends especially upon the matter interposed. If there is nothing between the insect and the plate, the rays emitted behave like ordinary light. They are capable of being reflected, refracted and polarized.

On the contrary, the rays transmitted by the cardboard or the copper plates possess properties that are analogous to those of the famous X rays. They appear to acquire these during their passage through the "filtering" substance, and vary with the latter. They are capable also of being reflected, but are neither polarized nor refracted. Finally, what is an interesting peculiarity to point out, these "filtered" rays possess some of the properties of the ultra-violet rays as well as of the Roentgen rays. Would it not be more logical, then, to admit that the lampyris emits two kinds of rays—the ordinary luminous rays and the Roentgen ones? This luminosity, which has defied the sagacity of investigators for ages, is very curious. Prof. Muraoka has desired to lift one corner of the veil. Has he succeeded in getting any nearer to a solution of the problem? That is the question. However this may be, it is our opinion that the last word has not yet been said.—La Nature.

THE "INDEX ANIMALIUM."

The number of species of recent animals already described has been computed by our zoological recorders as 386,000; including fossils, we may well put the number at 550,000. The number of names applied to those animals is, however, far greater. Owing to the ignorance or perversity of men, or to the gradual advance of knowledge, some animals are burdened with as many as twenty names, but—unlike "the ways of constructing tribal lays"—only one of them is right. Now, whatever be the principles that guide a systematist in determining the name that should be applied to a known species, it is clear that he must have all the claimant names before him when making his decision; and not only the names that have been applied to the species in question, but names applied to other genera and species, some of which may have received identical names. Consequently, as we have often urged, a complete list of all names that have ever been proposed is an indispensable preliminary to any effective revision of nomenclature. Such a list is the "Index Animalium," now being prepared under the auspices of a committee of the British Association.

It has already been shown in Natural Science (Jan., 1896) that the average number of names applied to each species mentioned in the British Museum Catalogue of Birds is 5¼. But on a more moderate estimate of three names to each known species in the animal kingdom, this index will have to contain no less than 1,650,000 references. The mere writing of these is almost a life's work; and to this labor must be added that of searching for scarce literature, or verifying dates—a most important part of the work—of interpreting obscure passages often in strange tongues, and of sorting

Fig. 3.—JAPANESE LADIES COLLECTING GLOW WORMS. (REDUCTION OF A JAPANESE PRINT.)

the slips into alphabetical order under genera. To this gigantic task, Mr. C. Davis Sherborn, an enthusiastic and competent bibliographer, has devoted himself. In the course of some four years he has completed 140,000 references, each on a separate slip and in duplicate. These are arranged under genera as the work goes on, so that they are always available for reference. Any zoologist can see them by applying at the library of the Geological Department of the British Museum (Natural History), and in this way or through correspondence many have already derived important help from Mr. Sherborn's labors.

Descriptions of the methods and progress of the work have recently appeared in the Proceedings of the Zoological Society (1896, pp. 610-611) and the Geological Magazine (Dec. iv, vol. iii, pp. 557-561, Dec., 1896); but, feeling that zoologists in general are not sufficiently aware of the service being rendered them, the committee has asked us to draw attention to it. We do so with great pleasure, and we earnestly trust that some practical expression of sympathy may be the outcome. The British Association was able last year to make a grant of £100 toward the work; but this does not go far, and there is no guarantee that a repetition even of this will always be practicable. To make satisfactory progress, at least £200 a year is needed, and the zoologists and paleontologists of the world should surely be able to provide that sum.—Natural Science.

THE COLOBUS VELLEROSUS.

THE COLOBUS VELLEROSUS.

OUR illustration shows a Colobus vellerosus, or silk monkey, as they are found in the territory between the Gold Coast and Dahomey, along the Gulf of Guinea. The colobi in general are remarkable for their long, silky fur, for the almost entire disappearance of the thumbs of the fore hands and for the tuft which they have on the end of their long tails. They are inhabitants of the virgin forests, where they live in companies on high trees, scarcely ever descending to the ground. They have a very clever way of hiding themselves in the foliage, by drawing together the branches beneath them. Commercially these colobi are of importance for their fur, which is imported into our civilized world, to be made into articles for winter clothing.

There are three varieties of colobi known. First there is the Colobus vellerosus, a specimen of which in the Hamburg Zoological Gardens has supplied the model for our illustration, taken from the Illustrirte Zeitung. The tuft on the end of the tail can be clearly distinguished. His cheeks are covered with a bushy white beard; the upper portion of his fore limbs is gray, all the rest of his body is black. His fur is long and silky all over. The monkey feeds on leaves, tender buds and shoots, and all sorts of fruit. A peculiarity of this particular colobus is that, when young, it is quite white, but it soon changes to the color of the adult.

A somewhat similar monkey, the Colobus ursinus, is found in Liberia and Sierra Leone. This variety has white shoulders. In the Congo State the Colobus satanas is the only representative of the class of colobi. He is, as his name implies, quite black. There are also olive colored colobi, which are characterized by a tuft of fur on their heads, and others colored variously from red to black and black and white.

THE TRUE PURPOSE OF A LARGE PUBLIC PARK.*

THE true purpose of a large public park is to provide for the dwellers in cities convenient opportunity to enjoy beautiful natural scenery and to obtain occasional relief from the nervous strain due to the excessive artificiality of city life.

By large public park is not meant one covering more than a certain number of acres, but one large enough to contain a complete natural landscape, where the boundaries will not be obtrusive; where city conditions will not be unduly apparent; where one may stroll over hill and dale, across meadows and through woods, always amid natural surroundings, for hours, without twice following the same routes; where one may come again and again without becoming familiar with all its interesting localities and natural features; where many thousands of visitors may be enjoying the scenery at the same time without crowding each other; where those who especially seek seclusion may find parts so remote from the boundaries that even if city houses are not completely hidden they become reduced in the distant perspective to inconspicuous proportions as compared with the foliage of trees and other natural objects in the foreground; so remote that the roar of street traffic is less noticeable than the rustle of foliage stirred by the breeze or than the songs of birds and insects.

That the scenery of such a park should be beautiful no one will deny, but that it should be natural needs explanation. There can hardly be such a thing as absolutely natural scenery in a public park near a large city. Fires, pasturing, cultivation, wood chopping, the destruction or driving away of the wild animals, wild birds and insects, and the introduction of others, have long since ended purely natural conditions about every large city, leaving at best only a general resemblance to natural scenery. Even if a tract of land is still to be found in a comparatively natural condition while in private ownership, it could not remain entirely in that condition after being properly fitted for and used as a public park.

With these limitations in mind, what is meant by the natural scenery of a large public park may be itemized as ordinarily either open meadow, open grassy hillsides or rolling ground, open groves of trees with good turf, dense woods, borders of shrubbery, or low woody or herbaceous undergrowth, water in river, brook, pond or pool, and more rarely cliffs or ledges of rock. These principal features of the scenery again may be divided into their elements of earth or rock surface, water surface and foliage, either ground cover, shrubbery or trees.

In most cases a good deal of grading needs to be done in places. The original natural surface is wholly or partially destroyed and a new surface is created artificially, but it should be so shaped and finished as to appear natural, or, at least, as closely in harmony with natural surfaces as study and care can make it. Too often, however, through lack of appreciation of the true purpose of a large public park, the grading which must be done, either ignorantly or carelessly, or owing to mistaken ideas as to economy, or owing to personal preference for artificiality, is made as regular and unnatural as possible, so that what might have been done in harmony with the natural scenery antagonizes it and greatly lessens its value for its true purpose. Abundant instances of artificial-looking grading in the wrong place exist in many of our large public parks. The responsibility of park commissioners for this sort of interference with the true purpose of a large public park is generally only in the indirect way of intrusting the work to men not properly trained in park work or by enforcing an unwise economy; for it must be acknowledged that to grade naturally and gracefully usually costs more than to grade formally and stiffly.

The water surfaces of a park need more study and care to make them appear natural in outline and as to their margins than does the general ground surface of the park. Too often park waters are almost as stiff and formal in their outlines and in the shaping of their shores as are the curvilinear distributing reservoirs of waterworks. Here, again, the park commissioners are indirectly responsible for the bad results in consequence of working without the plans and directions of a trained artist or without a foreman trained in producing natural effects in park grading.

The verdure of a large public park is what the eye rests upon almost everywhere, and it is therefore the most important of the natural elements of the scenery. The almost universal ground cover is grass, since no other plant is so well adapted to the purpose of hiding bare earth while enduring, with due care and under sufficient restrictions, the trampling of great numbers of people. But there are places where even grass will not thrive, or where a wider or more varied effect is desirable. Such cases are very generally ignored in our large public parks, owing to a lack of knowledge or of artistic appreciation of the possibilities or requirements of particular cases. If gardeners studied natural scenery more, they would almost surely discover many opportunities in parks for the application of what they observed in the country. For instance, a dense natural wood which need not be or cannot be well thinned out sufficiently to permit a good turf to be grown, so that people may properly be allowed to ramble everywhere in it, may often be rendered far more natural and interesting by planting pretty wild flowers in its margins and suitable shrubbery undergrowth in its interior. Again, steep, open banks, where it is difficult and expensive, and often unnatural, to maintain turf, can be made far more interesting by the use of low ground covering plants or shrubbery.

Relief from the nervous strain of an artificial city life is afforded in no way so agreeably and conveniently as by a ramble amid the natural scenery of a large park and by the leisurely contemplation of the landscape. There are many workers in a city who suffer more or less from nervous strain, though often they are not fully aware of it. Where a large public park with ample provisions of natural scenery has been created, it has never failed to be much frequented for this purpose and to afford untold benefit to those who use it. Not only are the quiet and seclusion obtainable in the middle of a large area necessary in affording opportunities for occasional relief from the nervous stress of our artificial city life, but they are necessary to the enjoyment of the landscape of the park. Therefore, not only should conspicuous artificial objects unnecessary for the convenient use of the park be excluded from its natural parts, but noisy and dangerous occupations and amusements should also be kept out of at least the middle portions of a large park. In order to have the essential quality of seclusion, a large park should not be attempted on both sides of a railroad or important city street if it is possible to avoid it, for even if the landscape could be made to seem continuous across the gap, the noise would almost destroy the desired seclusion of a considerable part of it. An extent of natural scenery sufficient to afford the sense of quiet and seclusion so beneficial to the city worker can only be secured where the grounds are ample, and therefore this should be the essential characteristic of a large park. It is the one vital reason for the existence of such a park. No number of small parks can possibly answer the same purpose, however useful and even necessary they may be for other reasons.

Even if the true purpose of a large park has been kept in view during the process of selecting the land, determining upon its landscape features, designing its necessary construction and plantations, it is too often lost sight of subsequently, and there is a marked tendency to artificialize the landscape. But whenever it is thought wise for a municipality to provide special attractions, these should be limited in kind and number and be carefully devised. It would not be wise or economical for a city to destroy or injure broad and beautiful park scenery by introducing artificial attractions into it when these could perfectly well be provided in the smaller squares or in special amusement grounds, which could usually be much nearer the center of population than a large park, and therefore could be used by more people more frequently and more cheaply. It is customary for cities to provide for certain kinds of amusements which are healthful and innocent, and for certain objects that are instructive and entertaining and for some that are artistic and in-

* From a paper read before the recent meeting of the Park and Outdoor Association of Louisville, Kentucky, by John C. Olmsted, of Brookline, Massachusetts.—From Garden and Forest.

spiring, and which cannot be or are not usually supplied solely by private effort. Such, for instance, are formal gardens, statuary, conservatories, botanical and zoological gardens, concert groves, electric and other fountains, fireworks and the like; also popular athletic grounds, parade grounds, ball grounds for boys, and facilities for boating and bathing. From motives of expediency, it is customary to include arrangements for some of these purposes in large public parks, but they should be placed in their borders, and in such a way that they will do the least possible injury to the more secluded parts of the scenery. Great discrimination is necessary in selecting among these objects those which will least interfere with the primary purpose of a large public park. Those forms of amusement or instructive entertainment requiring large buildings or implying much noise, or which draw large and careless crowds that would be liable to injure the grass and shrubbery and trees of the park, should be excluded. It is good policy to secure suitable lands adjoining a large park which can be held in reserve as sites for public museums, grounds for parades, fireworks, public speaking, baseball and (by flooding in winter) for skating and so on. The park in Brooklyn is exceedingly fortunate in having two very commodious public grounds adjoining it. It is greatly to be desired that other cities should do likewise.

If there were a well established and clearly recognized custom controlling what artificial features might and what should not be introduced into large public parks, such customs would develop into rules of common law. Or if there had been carefully drawn and detailed statutes passed upon the subject, or if there had been a series of decisions of courts as to what buildings and other objects could legally be introduced into public parks, their true purpose would be more clearly understood. It is true, there has been for years a statute in New York State forbidding the erection of buildings above a certain size not strictly for park purposes in any public park, but the principle upon which this law is based is so little understood that a few generous individuals recently had no difficulty in getting a special law passed which enables them, with the consent of the park commissioners, to introduce a great museum of history into one of the most beautiful landscapes of one of the most perfect large public parks in the world. The usual arguments in support of this desecration have been urged, namely, that the building is for a worthy semi-public object; that the collection it is to contain will be interesting and instructive to the public, and that the building itself will be handsome, and consequently that it will be an ornament to the park. If this argument is sound for one such building, it is equally sound for others. In that case a large public park is little more than a tract of beautiful vacant building lots which the public is temporarily enjoying as a playground until it shall be gradually required for one public or semi-public building after another. If there is no principle upon which the advocates of the first semi-public building can be refused a site, there is no logical reason for refusing sites to any subsequent projects of a like sort. The bars once let down, there will be a stampede to secure beautiful building sites free of cost for natural history, art, botanical and other museums; for armories, normal colleges, high, grammar and primary schools, and so on almost indefinitely.

MONAZITE.*

By H. B. C. NITZE, E.M., Chemist to the Wetherill Concentrating Company, South Bethlehem, Pa.

IT has only been within the past few years that monazite has become one of the important economic mineral products, in its use for the manufacture of the incandescent mantles of the Welsbach light. Previous to that time it was considered one of the rare minerals, as denoted by its name, a derivation from the Greek, meaning "to be solitary."

The demand created by the manufacturers of the incandescent gas lights for the rare earth minerals stimulated the search for monazite, and it was soon found to exist in certain deposits and rocks, where its presence had not before been suspected, and so necessity became the mother of discovery.

Monazite is essentially a phosphate of the rare earths, cerium, lanthanum and didymium (Ce, La, Di) PO_4. It also contains, almost always, small variable percentages of thoria (ThO_2) and silica (SiO_2), which by some are supposed to be present in combination, as an impurity, in the form of thorite or orangite ($Th.SiO_4.H_2O$), while others believe that the thoria is a primary constituent, present originally as the phosphate, either in combination with cerium or as an isomorphous compound, and afterward altered to the silicate by siliceous waters.

Several typical analyses, made by Prof. S. L. Penfield,† of Yale University, are appended:

	1.	2.	3.	4.
P_2O_5	28·18	29·28	26·12	29·32
Ce_2O_3	33·54	31·38	29·89	37·26
La_2O_3	28·33	30·88	26·66	31·60
ThO_2	8·25	6·49	14·23	1·48
SiO_2	1·67	1·40	2·85	0·32
H_2O	0·37	0·20	0·67	0·17
	100·34	99·63	100·12	100·15

(1) From Portland, Conn.; (2) from Burke County, N. C.; (3) from Amelia County, Va.; (4) from Alexander County, N. C.

Monazite crystallizes in the monoclinic system. The usual crystal habit is tabular, parallel to the orthopinacoid (∞ P $\bar{\infty}$); also short columnar, and sometimes elongated in small needle-shaped crystals in the direction of the prism (∞ P). The crystals are usually well developed and free from distortion. They vary in size from microscopic needles, having a thickness of only 0·0015 to 0·0062 in., to the abnormally large and rare crystals that have been found in Amelia County, Va., 5 in. in length. The more usual size, however, lies between 0·05 and 1 in.

The cleavage is most perfectly developed parallel to the basal pinacoid (oP); it is also distinct, as a rule, parallel to the orthopinacoid (∞ P $\bar{\infty}$), and sometimes parallel to the clinopinacoid (∞ P ∞).

The mineral is brittle, with a conchoidal to uneven fracture.

The hardness is 5 to 5·5. The specific gravity varies from 4·6 to 5·3. The luster is resinous to waxy, and the crystal faces are splendent in the fresh, pure specimens, and dull in the weathered, impure specimens, the surfaces being sometimes coated with a light brown earthy substance, probably an alteration product.

The purest specimens are transparent, becoming translucent and even totally opaque in the impure varieties.

The color is honey yellow, amber yellow, yellowish brown, reddish brown and sometimes greenish yellow.

Monazite is an accessory constituent of the granitic rocks and their derived gneisses. It has been found in these rocks over widely separated regions of the earth's surface, and further search and study is liable to reveal its probable universal presence in most granites and gneisses. It has also been found in apatite, cyanite, and even in vein quartz. The main constituents of the granitic rocks (quartz, feldspar and mica) all contain the monazite as intergrowths, though it appears to be more generally confined to the feldspar. Zircon may be regarded as a constant accessory, and among the other usually associated minerals may be mentioned garnet, rutile, ilmenite, magnetite, xenotime, fergusonite, gadolinite, sphene, cassiterite, corundum, etc.

Monazite has not been found in the sedimentary rocks, although it may be present in some of these as a re-deposited mineral.

The economically valuable deposits are found in the placer sands of streams and rivers, in the irregular sedimentary sand deposits of old stream beds and bottoms, now covered up, and in the beach sand deposits along certain seashores.

In the southern unglaciated countries the decomposition and disintegration of the crystalline rocks, the original source of the mineral, have proceeded to considerable depths. By erosion and secular movement the loose material is deposited in the stream beds, where it undergoes a natural process of sorting and concentration, the heavy minerals, and among them the monazite, being deposited first and together. The richer portions of these stream deposits are therefore found near the head waters.

The beach sand deposits have a similar explanation, the concentration in this case being brought about by the action of the waves.

The geographical areas over which such workable deposits have been found up to the present time are quite limited in number and extent. In the United States the placer deposits of North and South Carolina stand alone. This area comprises about 2,000 square miles, situated in Burke, McDowell, Rutherford, Cleveland and Polk Counties, North Carolina; and Spartanburg, Greenville and York Counties, South Carolina.

The country rocks are granitic biotite gneiss and dioritic hornblende gneiss. Most of the stream deposits have been worked for gold. The thickness of the gravel beds is from 1 to 2 ft. and the width of the mountain streams in which they occur is seldom over 12 ft. The percentage of monazite in the gravel is very variable, from an infinitesimal quantity up to 1 or 2 per cent.

In Brazil extensive deposits of monazite occur in the beach sands along the sea coast. The largest of these is on the island Alcobaca, in the extreme southern part of the province Bahia.

Deposits are also found in the gold and diamond placers of the provinces Bahia (at Salabro and Caravellas), Minas Gieraes (at Diamantia), Rio de Janeiro and Sao Paulo.

In the United States of Columbia deposits of importance are reported in the gold placers of the Rio Chico, at Antioquia.

In Russia the mineral is found in the Bakakul placers of the Sanarka River in the Ural Mountains; also in the placer mines of Siberia.

In North and South Carolina the monazite is won by washing the sand and gravel in sluice boxes with a stream of water, exactly after the manner that placer gold is worked. The sluice boxes are generally about 8 ft. long by 20 in. wide by 20 in. deep. Two men work at a box, the one charging the gravel on a perforated plate fixed in the upper end of the box, the other one working the contents up and down with a gravel fork or a perforated shovel in order to float off the lighter sands. The boxes are cleaned out periodically, depending on the richness of the gravel and the consequent degree of accumulation of the concentrated monazite.

From 40 to 70 pounds of cleaned monazite per box is considered a good day's work.

Sometimes two or more boxes are used, arranged in a series of steps, one below the other

Magnetite, if present, is eliminated from the dried sand by treatment with a large hand magnet. Many of the heavy minerals, such as zircon, garnet, rutile, ilmenite, etc., cannot possibly be completely eliminated by any means of water separation, owing to the slight differences of their specific gravities.

The commercially prepared sand, therefore, after washing, is not absolutely pure monazite. A sand containing 65 to 70 per cent. monazite is considered a good quality.

Some operators endeavor to clean the water concentrated sand still further, by pouring it, after it is dried, from a small spout situated in the bottom of a hopper, in a fine steady stream from a height of about four feet on a level platform; the lighter particles (quartz, feldspar, etc.) together with the finer grains of monazite, garnet, rutile, etc. (which might be called tailings), fall on the periphery of the conical pile, and are constantly brushed aside with hand brushes; the tailings are afterward rewashed. Instead of pouring and brushing, the material is sometimes treated in a winnowing machine similar to that used in separating chaff from wheat.

Although the grade of the sand may in this way be brought up to eighty-five per cent. pure, the quantitative proportion is small as compared with the second and other inferior grades, and there is always a considerable loss of monazite in the various tailings.

It is impossible to conduct this washing operation without loss of monazite, and equally impossible to make a perfect separation of the garnet, rutile, ilmenite, etc., even in the best grades. The additional cost of such re-treatment and re-handling must also be taken into consideration.

A marked improvement in the economy and perfection of the treatment would be to size the raw material, separate the quartz and lighter minerals by jigging, and subsequently separate the heavy minerals, garnet, rutile, etc., in the jig concentrates, by passing over a Wetherill magnetic separator.* Experimenting in this direction, I have succeeded in making a practically perfectly clean monazite product, with but an insignificant loss in the tailings.

If the raw material contains gold, it will be collected in the sluice boxes or in the jig concentrates, and it may frequently pay to separate it, which can be readily accomplished by treating the wet concentrates in a riffle box with quicksilver.

The monazite in the stream beds of the Carolina fields has been practically exhausted, and the last mining operations were carried on, for the most part, in the old gravel deposits and channels of the adjoining bottom lands. These deposits are mined by sinking pits, about eight feet square, to the bed rock, and raising the gravel by hand labor to sluice boxes above. The over-lay, which may vary from three to five feet in thickness, is thrown away, excepting in cases where it carries any sandy or gritty material. The pits are carried forward in parallel lines, separated by narrow tailing banks, similar to the method pursued in placer gold mining.

It has been shown that the monazite occurs in place as an accessory constituent of the country rocks, and that the latter are decomposed to considerable depths, sometimes as much as 100 feet. However, on account of the minute percentage of monazite in the mother rock, it is usually impracticable to economically work it for monazite alone, by such a process as hydraulicking and sluicing, for instance. Where the decomposed rock is gold bearing, and this is sometimes the case, it may pay to recover the monazite as a by-product. In certain instances the decomposed gneiss, in situ, has been found sufficiently rich in monazite to warrant working it.

The value of monazite depends on its percentage of thoria, as this is the element mostly sought after by the incandescent light manufacturers. And, as the percentage of thoria is variable in different sands, the value of the sands is consequently also variable.

The only method for determining the percentage of thoria is by chemical analysis. The fluctuation of the thoria is considerable even in the same locality. It also depends, of course, in a measure, on the degree of concentration of the sand. Some monazite contains practically no thoria. The best Carolina grades carry from four to seven per cent.

The price of Carolina monazite has varied from twenty-five cents per pound in 1887 to as low as three cents for interior grades and six to ten cents for the best grades in 1894 and 1895. In 1896, the price fell so far below this mark as to render the mining unprofitable and practically cripple the industry. This was owing to the development and increased output of the Brazilian field, where the sand occurs naturally concentrated on the beach, and requires no cleaning treatment for shipping, after it is dug out. Being loaded directly into the ships' holds as ballast and transported by water, the freight costs are also considerably less.

In 1893, the output of Carolina monazite sand was 130,000 pounds; in 1894, 546,855 pounds; in 1895, 1,000,000 pounds; and in 1896, for reasons above named, it fell to 17,500 pounds.

RECENT ARCHÆOLOGICAL DISCOVERIES IN THE NILE VALLEY.

M. JACQUES DE MORGAN, the director-general of antiquities of the Egyptian government, has just forwarded to his brother, M. Henri de Morgan, of this city, particulars of his latest find in the ancient Nile Valley. The letters tell of one of the greatest Egyptian discoveries that have ever been made. They describe the finding of the tomb and mummified body of Egypt's probable first king, who is supposed to have reigned 4800 B. C., or almost seven thousand years ago. According to archæologists, the importance of this discovery cannot be overestimated. M. de Morgan is one of the greatest Egyptian explorers. Many finds of inestimable value can also be placed to his credit, and a large portion of the contents of the imperial museum of antiquities at Gizeh evidences his success in ancient Egyptian discoveries. During the greater part of last year he paid special attention to the study of prehistoric man in the Nile Valley; and in that portion of the valley formed by the bend in the Nile between Thebes and Abydos he unearthed many of the oldest records pertaining to early Egyptian history that have yet been found. From these records it became apparent that at one time, in the extremely remote past, Abydos was the capital of Egypt and the city that contained the tomb of Osiris, the oldest tomb of which tradition speaks. It was to investigate over again this remarkable ground that M. de Morgan began his search. Working steadily by means of trenches and soundings, the first notable discovery was made in the shape of ancient flint arrow heads. These were of the most remarkable kind, and evidently belonged to a period considerably antedating the time of the fourth dynasty, which up to this time had been the most remote age of which science had any record. Other implements were found in the shape of indented flint blades, which had probably been used as saws and sickles. This was determined from the fact that wheat is believed by historians to have grown wild in Egypt at the time of the first dynasty, and the shape of the implements found indicates clearly that they were used for harvesting this wild cereal. A complete specimen of one of these sickles, in its wooden setting, was found deeply buried in the sand. This sickle indicates that the people of the first dynasty were advanced in the art of agriculture, as well as accustomed to the use of flint tools.

M. de Morgan also found evidences that these ancient people had a religion of their own, in the shape of slate figures of fishes, birds and turtles, which he dug up. He believes the religion to have been a sort of fetishism, as he can in no other way explain the curious images. Regarding this point he says: "These figurines must have belonged to either the first dynas-

ty or to a race and period preceding it, as I have found them only in these autochthon places. Of this fact there is no doubt, as the figurines were unearthed under my own eyes, and I must add that not in any of the other old tombs of the ancient empire that have been discovered have I ever found the slightest fragment." Continuing his soundings and study of the ground, M. de Morgan slowly made his way along the valley until he reached a point near Negada, where an extraordinary mound attracted his attention. So out of the usual nature of the ground was it that he determined upon an investigation. Excavations were begun at the base of the north side of the mound and revealed the existence of a huge quadrangular shaped tomb. As soon as this discovery was made a camp was established and work commenced in earnest. Numerous attempts were made to pierce the solid sides of the tomb, which from the nature of the surroundings, the explorers believed to be intact. Finally, on one side an opening was made, which was gradually enlarged to the size of a large doorway. Long, gloomy passageways descended down into subterranean depths. They passed through the rows of wonderfully carved columns, down the hollow passageway, to the caverns below. From top to bottom the walls were covered with hieroglyphic inscriptions, and cut deeply into the surfaces were outlined the figures of men and animals that had lived and died five thousand years before the Saviour walked the earth. Strange characters of warriors, different from anything seen in other tombs, stood out in bass-relief, and the images of children, kneeling as if in fear, appeared here and there on the sides of the passageways.

Taking the main aisle, they followed it by torchlight, and found that it led into a series of rooms. In all there were twenty-one of these rooms, each containing many objects. In the center of each were placed sarcophagi containing the mummified remains of the dead, and around them were scattered many objects of the utmost antiquity. There were a number of pieces of what had once been furniture, in several different designs, and here and there fragments of bronze statues lay in the dust. In almost every one of the rooms a quantity of broken vases was found. These bore evidences of having been made of alabaster or some similar stone, and were of the most peculiar and wonderful designs. Still other vessels were found cut out of the hardest materials, such as rock crystal and quartz. How these remarkable people managed to cut such hard substances, or the methods and tools they had for doing it, is a mystery. There were a number of implements found in several of the rooms, but they were all of flint. It is nevertheless evident that they must have possessed some other instrument, harder even than flint, to have been able to make such carvings. Several vessels made from a substance resembling obsidian were also found. From one room to another the explorers went until they discovered a large central room. In the center, upon a pedestal of solid rock, rested a single huge sarcophagus. Around it, rudely carved in ivory, were the forms of fishes and dogs in strange and grotesque shape. Near the feet were the remains of what appeared to have been a mammoth lion, made of countless pieces of ivory mysteriously put together. The sides of the room were covered with inscriptions of a period so remote that interpretation was impossible. At the head of the great sarcophagus and facing it was the life size statue of a man carved in wood. The explorers then opened the sarcophagus and exposed to view the inner mummy case, which was covered with hieroglyphics. So important was this discovery that no attempt was made to open the mummy case for fear the body, coming in contact with the air after being sealed up for so many centuries, would at once crumble into dust. The sarcophagus was again closed and sealed, after which it was prepared for removal to the museum at Gizeh, where the body will be carefully unwrapped.

Attention was then devoted to the sarcophagi in the other rooms, all of which were supposed to contain the bodies of royal persons. These have also been removed to the museum, where they will be opened. M. de Morgan then began the removal of the various articles from each of the rooms. In all of them he found large urns tightly closed and having on the top what is known as a "banner name," or the seal of the King. The presence of these "banner names" is regarded by archæologists as conclusive proof of the great antiquity of the tomb. The large wooden statue in the king's chamber was next studied. It was finely proportioned and was placed at the head of the sarcophagus in order to provide a resting place for the king's soul in case anything happened to injure the body. M. de Morgan says that the rulers of these early dynasties deemed it absolutely essential that their bodies should exist in a perfect condition until the time of the corporeal resurrection of the royal dead. According to their belief, the living man consisted of four parts—a body, a soul, an intelligence, and an appearance, or double. Death disassociated these four parts, which, according to the belief, would ultimately be reunited for all time. If upon the return of the soul the real body was in any way injured, the soul immediately took refuge in the wooden image. The inscription on the walls of this wonderful tomb, like those of a later date, pictured the achievements and elaborate funeral rites and texts of the royal inhabitant. They showed him in the height of his glory and again lying in mummified form. A series of pictures represented the body being conveyed on a great sledge across a sacred valley to the tomb. The sledge was drawn by oxen and men and followed by many mourners. The pictures indicated that at that period of the world's early history the greatest ceremony of a king's life was his funeral, and the ceremony must have extended over a great many days, judging from the gorgeous rites that were performed. The ceilings of all the passageways and rooms in the great tomb were lined with what appeared to be sun-dried brick, although the bricks were of very coarse workmanship. The pavements of the floors were of granite, and here and there were traces of wooden coverings. Until this discovery by M. de Morgan, nothing had been found to throw any light upon the beginning of Egyptian history.—The New York Herald.

A bronze statue of Marcello Malpighi has been erected at Crevalcore, near Bologna. The Royal Society sent an address of congratulation, Malpighi having contributed many valuable papers to their Transactions.

THE DANGER IN VEILED STIMULANTS.

THE medical profession and the laity have been accustomed for so many years to the abuse of alcohol as a nervous stimulant that some persons have become hardened to the miseries which it induces, while others have been stimulated to its excessive condemnation. As a result of this and of the general desire for stimulating foods or drugs, a very large number of persons have been led to place before the public other powerful nervous stimulants, of which both the medical profession and the laity know less than they know of alcohol, until at the present time there are almost as many consumers of nervous stimulants other than alcohol as there are of those who use alcohol to excess. Further than this, the number of these substitutes is daily increasing, and in many instances unprincipled venders are fortifying comparatively innocent and solid nervous stimulants, dispensed for common use, with so large a quantity of alcohol added that the patient really becomes addicted to the alcohol habit. The object of this is not, however, to direct attention to these preparations or to the evil effects which they produce, but rather to make clear the fact that all of them are but temporary makeshifts which in the end, in the vast majority of cases, materially increase the discomfort and the ill health of the person who takes them.

The abuse of these remedies by the profession is not so much the result of ignorance as of carelessness. There is no drug yet discovered, so far as we know, unless it be alcohol, which distinctly adds force to the body when it is taken. All of the so called "strengthening remedies," which enable a man to accomplish more work when he is under their influence, do this, not by adding units of force to his body, but by utilizing those units of force which he has already obtained and stored away as reserve force by the digestion of his food. Kola, coca, excessive quantities of coffee and tea, and similar substances, while they temporarily cause nervous work to seem lighter, only do so by adding to the units of force which a man ought to spend in his daily life those units which he should most sacredly preserve as a reserve fund. The condition of the individual who uses these remedies when tired and exhausted, with the object of accomplishing more work than his fatigued system could otherwise endure, is similar to that of a banker who, under the pressure of financial difficulties, draws upon his capital and reserve funds to supplement the use of those moneys which he can properly employ in carrying on his business. The result in both instances is the same. In a greater or less time the banker or the patient, as the case may be, finds that his reserve fund has disappeared and that he is a pecuniary or nervous bankrupt.

Even the advertising boards and fences of the cities, towns and country now contain advertisements which mislead the ignorant into the idea that, by using the drugs named thereon, they will actually increase the development of their muscular power, when in reality the final result of such a course must be to decrease the nervous stamina which the would-be athlete so earnestly desires.—Therapeutic Gazette.

THE ETIOLOGY OF YELLOW FEVER.

E. KLEIN, in Nature.

YELLOW fever is an acute infectious disease, endemic in the West Indies, the shores of the Mexican Gulf, and in some parts on the west coast of Africa, whence the disease has been repeatedly transported into other localities, causing epidemic outbreaks. Like other infectious diseases, yellow fever is supposed to be caused by a specific living entity which, invading a predisposed person, multiplies there and causes the peculiar pathological changes in the gastro-intestinal tract and the liver characterizing yellow fever. Within recent years the supposed specific microbe has been discovered several times. Dr. Domingos Freire, of Brazil, and Dr. Carmona y Valle, of Mexico, have announced such discovery, but Dr. Sternberg, of Washington, who has himself studied the disease on behalf of the United States government, has shown that none of these discoveries is a reality, and after a prolonged investigation, including the examination of a great many cases affected with or dead from the disease, has arrived at the following conclusions, embodied in a lengthy report to his government: that none of the different species of bacilli and cocci, present in the intestinal canal, in the blood, the liver and other tissues of persons affected with yellow fever, can have a claim to be considered as the specific microbe; that in a number of cases the examination, microscopic and cultural, of the blood and tissues yielded no bacteria recognizable either by the known methods of staining or culture; and he finally implied that the specific microbe of yellow fever is most probably not of the nature of a bacterium at all. After these very definite conclusions by Dr. Sternberg, it came rather as a surprise when, some months ago, the announcement was made that Dr. Sanarelli, Professor of Experimental Hygiene in Montevideo, formerly in the Pasteur Institute in Paris, had discovered the true cause of yellow fever in the form of a bacillus, Bacillus icteroides. This surprise is still further heightened by the statement in Dr. Sanarelli's lecture, that the Bacillus icteroides is demonstrable by the ordinary methods of staining and by culture in the ordinary well-known media. The morphological and cultural characters of the bacillus show it to belong to the group of coli-like bacilli; it is rarely demonstrable in a pure state in the blood or tissues, being generally associated with a more or less copious admixture of other microbes—Bacillus coli communis, streptococci and staphylococci; as a rule it is present only in small numbers in the capillary blood vessels of the liver, spleen and kidney. It reflects great credit on the perseverance and sagacity of Dr. Sanarelli to have been able, notwithstanding all these difficulties, to select out the Bacillus icteroides, and to have by animal experiment been able to demonstrate, at least, as highly probable that the Bacillus icteroides is the true microbe of yellow fever. As mentioned just now, the distribution of the microbe in the affected person, its morphological and cultural characters, do not in themselves offer strong prima facie evidence, and Dr. Sanarelli himself fully recognizes this; but when we come to the experimental evidence which he furnishes, the evidence as to the Bacillus icteroides being the specific cause of yellow fever assumes considerable power.

In the first place, Sanarelli shows that dogs, goats and horses are susceptible to infection both with the living bacilli as also and particularly with the highly poisonous toxin produced by the bacilli in broth culture; the symptoms and anatomical lesions hereby produced in these animals in the intestinal tract, the liver and the kidney, bear a striking resemblance to those of yellow fever in man. In the second place, Sanarelli furnishes proof that the toxin produced in broth culture—and separated from the bacillary growth by filtration through a Chamberland filter—when injected into healthy persons causes a prompt reaction in the form of severe disturbance, primarily of the intestinal tract, but also, further, of the general system closely resembling that in yellow fever. It is to be hoped, nay, it may be assumed as certain, that in continuing his investigations Dr. Sanarelli will ascertain the action of the blood of human beings, who have passed through and recovered from the disease, on the Bacillus icteroides. This disease, as is well known, very rarely occurs twice in the same person, and it is therefore highly probable that, as is the case in other similar infectious diseases, the blood after a single attack possesses agglutinating action (in vitro), or germicidal action (in corpore), or both on the culture of the specific microbe. If on further investigation the blood serum, after an attack of yellow fever, should be found to show such positive actions on the Bacillus icteroides, a strong support will thereby be furnished as to this bacillus being the specific microbe. It will be the crowning of prolonged and laborious studies if Sanarelli by experiments on immunization of animals—the horse being evidently well fitted for such immunization—did, as is highly probable that he will, obtain antitoxic serum by which yellow fever can be successfully combated both prophylactically and therapeutically.

ORIGIN OF FAT IN THE BODY.

THE subject of the origin of fat has once more been taken up by the experimentalist. Many years have now elapsed since the well-known French chemists, MM. Dumas and Boussingault, as the outcome of their researches, maintained that animals, whether herbivorous or carnivorous, were supplied with all their proximate principles by the vegetable kingdom—the former class directly, the latter indirectly through the herbivora on which they preyed. Animals, according to these observers, did not make fat, sugar or albumen, but derived each and all of these substances from plants. This position was contested by Liebig, who contended in regard to fat that this was not altogether obtained by animals from the fat of their food. On the contrary, they were able to make it with either sugar or starch. He pointed out, as Huber had done before him, that bees fed on sugar or honey alone were capable of forming fat in the form of wax, but Huber had omitted to weigh the bees before dieting them, and Dumas and Boussingault ingeniously argued that the wax formed on a diet of pure farina or sugar was originally stored up in the bodies of the bees and utilized by them in the construction of their combs. Liebig therefore still supported the view of Huber, and held that the greater part of the fat which is deposited in the animal body and that which is found in the milk of nursing mothers is formed in the body and almost exclusively from the hydrocarbonaceous compounds of the food. The albuminoids, he thought, played quite a subordinate rôle from this point of view, as, indeed, seemed probable when it was considered that the food of the herbivora which store up much fat is chiefly composed of carbohydrates, while the bodies of the carnivora, whose food is chiefly albuminous, contain little or no fat. Moreover, he experimented on a goose, which from a lean condition was fattened to such an extent that three pounds of fat was obtained from it, although the maize with which it had been fed did not contain anything like that quantity of fat. Dumas and Boussingault returned to the charge by making a careful analysis of the food given to a cow for a year and determining the quantity of fat which the animal yielded in the milk. They found the fat introduced with the food to be considerably in excess of that eliminated by the milk, but Liebig scored a point by observing that nearly all the fat ingested with the food escaped undigested from the bowels in the feces. Subsequent experiments, especially those of Lawes and Gilbert, on the herbivora clearly demonstrated that one, at least, of the sources of fat is the farinaceous material ingested. In the meanwhile various circumstances had led some investigators to adopt the view that the albuminoid or nitrogenous constituents of the food might play a part in the generation of fat.

Thus it was found that animals fattened best when their food, if chiefly farinaceous, was mingled with some albuminous compounds; while Pettenkofer and Voit demonstrated that in a dog freely supplied with flesh the whole of the nitrogen thus introduced into the economy was recoverable from the urine and feces, while the carbon remained in the economy and hence, probably, formed or aided in the formation of fat. The observations of Kemmerich on nursing bitches, of Subbotin of feeding dogs with palm oil and meat, of Hofmann on larvæ fed on defibrinated blood containing a known quantity of fat, all pointed in the same direction and led Voit to maintain, first, that the fat of animals is exclusively formed from the proteid aliments, and secondly, that hydrocarbonaceous compounds are not converted into fat in the animal organism, but simply preserve from oxidation the fat formed from the proteids. The latest researches on this point, however, are not quite in accordance with Voit's views. The most recent observer, Dr. Kaufman, arrives at the following conclusions: The proteids, in common with the ternary compounds of the food, contribute to the formation of fat, but, contrary to Voit's statement, they are not the exclusive origin of it. When, during digestion, a large quantity of proteids is absorbed it rapidly undergoes disintegration and forms fat. This fat has, speaking generally, three applications. One part oxidizes and, passing through the phase of glucose, supplies the requisite energy for the general physiological work of the organism; another part undergoes incomplete oxidation and is transformed into carbohydrate which is stored up in reserve as glycogen; while the third part remains intact and is deposited as fat. The proportion of fat which is fixed during the digestion

period varies with the abundance of the repast and the richness of the organism in glycogen. If the animal is poor in glycogen, it may happen that the whole of the non-oxidized fat may be converted into glycogen. Calorimetric investigations demonstrate that if the anaerobic decomposition of albumen really occurs, the process is not attended with any disengagement of heat.—Lancet.

THE SKIN AS A DIAGNOSTIC FACTOR IN DISEASE.*

THE design of this paper is to deal with the conditions in which the state of the skin is liable to mislead the physician as to the cause of the illness of the patient. Sometimes, too, we are too much inclined to treat the skin affection as the only lesion of importance, and fail to connect it with the underlying condition of the system which is largely responsible for its development. These underlying provoking or predisposing agents are exceedingly numerous, and are perhaps best summed up or described in a very original manner by Dr. Stephen Mackenzie as follows: The seven stages of man could be well illustrated by diseases of the skin, though we lack a Shakespeare to do justice to the theme. In the "mewling and puking" infant we meet with sclerema and edema neonatorum, the "red gum" or strophulus of the older writers, intertrigo, eczema, urticaria papillosa (lichen urticatus), urticaria pigmentosa, xeroderma pigmentosum, and impetigo; "the schoolboy," with his chilblains and ringworm, alopecia areata, pityriasis rosea, ecthyma, and "football disease;" and then the "lover," with his acne and sycosis; and then the justice, with acne rosacea, diabetic boils, and pruritus ani; the sixth stage shifts into the "lean and slippered pantaloon," with rodent ulcer and "gouty" eczema; "last scene of all, sans teeth, sans eyes, sans taste, sans everything"—except an incessant and intolerable itching of the skin which we call senile prurigo.

Aside from these dermal manifestations of systemic states I believe that too little importance is given to the very common lesions of the skin following the use of drugs. The moment we leave the cases in which the eruption seems to arise without apparent cause, and approach the question as to the eruptions which may be produced by drugs, we pass into an almost limitless field. Only a few of the moderately common accidental rashes can be considered in the short space that can be devoted to this paper. As a rule, we are apt to regard iodoform as a very innocent substance, rarely producing untoward effects unless its application is exceedingly free, and then causing only general systemic symptoms of poisoning rather than skin manifestations. Usually this iodoformic rash appears when the drug is freely applied over a large surface, coming out generally within a few hours after the iodoform is applied (Meunier) and rarely after the twelfth day (Taylor).

It is a well-known fact to many more physicians than those who know of iodoform rashes that quinine is very apt in certain persons to produce skin eruptions of all kinds and varieties. In France, articles by Grellety, Dumas, and theses by Bonvard du Grissac and Levassor have recorded many cases, and a very large number of Americans have done likewise. Guirard states that in most cases, simultaneously with the ordinary symptoms of cinchonism, we have developed a roseola, a simple erythema, or a marked scarlatinal erythema. In other cases an acute eczema or urticaria comes on. I have seen this so-called quinine rash more than once. Usually the eruption is widely diffused, but, if limited, it may be found only about the breastbone or groin. If the eruption appears on the face, it is usually a tumefaction or edema. Its development is rapid and it soon reaches its greatest intensity, rarely persisting more than seven or eight days after the drug is stopped. Desquamation nearly always occurs. A differential point of value is that the eruption appears a second time if another dose is given.

Opium, on the other hand, is not usually suspected of causing eruptions on the skin. As a rule, the eruptions produced by it are limited to the face, but sometimes they are generalized. More commonly they are true erythemata and sometimes scarlatinal in type. In some cases there may be great redness of the skin, abundant sweating, acceleration of the pulse, heat of the skin. According to Brugisser, these symptoms often ensue after small doses, such as ten drops of laudanum. Finally we may discuss the skin lesions produced by turpentine. These follow both its internal and external use. As long ago as 1824 Barbière, in his work on "Materia Medica," and in 1841 Galtier, in a similar volume, described the onset of erythematous rashes, vesicles, and papules of very fleeting character after the ingestion of turpentine. Trousseau and Pidoux, in their book on "Therapeutics," have done likewise, but all these occurred after large amounts of the drug had been used or after its external employment. In 1879, however, Cordes published an early case of true turpentine rash following its internal use. In this instance a patient of thirty-four years, after the ingestion of turpentine, developed an erythema over the skin of the trunk. Another case observed by the same author was that of a woman who developed a marked urticaria under similar circumstances. In both these cases the eruption was very fleeting in duration.

The conclusions reached by Guirard are as follows: that medicinal eruptions are commonly limited to the face, afterward extending to the trunk symmetrically, and usually developing suddenly, as does erysipelas. Unless they arise from very large doses, they generally develop without being associated with general systemic symptoms. He thinks that the absence of these symptoms aids us in separating these cases from the infectious diseases. The eruptions due to drugs often change from one type to another, particularly those due to the balsams. The eruptions are usually sudden in onset and develop rapidly.

The word temper, as used in steel manufacture, means the percentage of carbon which the metal contains. For instance, in steel of razor temper, there is 1½ per cent. carbon; saw file temper, 1¼ per cent. carbon; tool temper, 1⅛ per cent.; spindle temper, 1¼ per cent.; chisel temper, 1 per cent.; set temper, ⅞ per cent.; and die temper, ¾ per cent. of carbon.

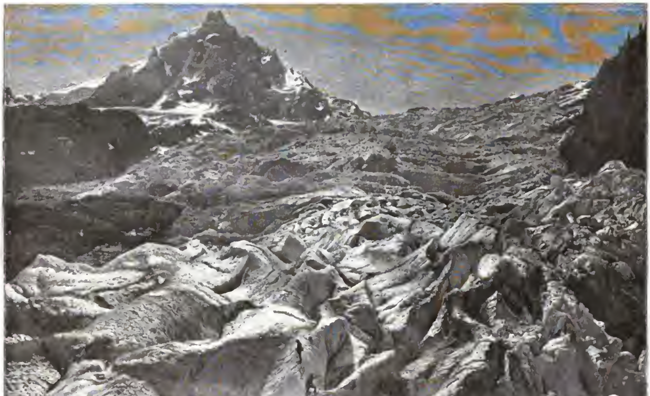
THE JANSSEN OBSERVATORY ON THE SUMMIT OF MONT BLANC.



THE BOSSON GLACIER AND THE AIGUILLE DU MIDI.

MONT BLANC.

THAT portion of the Alps in which is located Mont Blanc is characterized not only by the fact that within it lies the highest point of Europe, but by a striking peculiarity in its formations. Its wealth in unusually fine glaciers, the number of so-called séracs (ice needles), scattered over it, and its aiguilles are quite typical of the region.

The nature of the séracs and the difficulties met with in their ascent are well brought out in one of our cuts, which shows a party of tourists, led by experienced guides, slowly making their way up one of these ice blocks on Mont Blanc. But still harder to reach than the tops of these séracs are the summits of the aiguilles.

It is said that, after an ascent of some of them, the summit of Mont Blanc is reached with relative ease. One of these aiguilles, the Aiguille du Midi, is visible in the background of our second illustration. In the foreground extends the Bosson Glacier, one of the finest of that region. A striking characteristic is its rugged surface. Over its ridges we see proceeding a party of tourists, roped together and equipped with alpenstocks. A little hut at Pierre Pointue, on the way to the summit of Mont Blanc, commands a fine view over the glacier and its surroundings. Here, at a height of 6,650 feet, tourists rest on their ascent.

The view spreads over to the aiguille and the Dôme du Goûter, both covered with snow, and nearer by lies the little town of Chamonix. From Chamonix the ascent to Mont Blanc is often started. The way leads past the place where the Glacier de Taconnaz joins the Glacier des Bossons. This place is commonly known as the Passage de la Jonction. We reproduce a view of the spot. Two tourists are seen making the somewhat dangerous passage, linked together by a rope.

We have brought before our readers some scenes as the traveler meets them on the ascent of Mont Blanc. We will close with a few words to accompany our first illustration, which shows the aspect of the spot where the tourist finds his goal reached. On the summit of the Alpine giant, amid eternal snow, is built a little stone house, the Janssen Observatory. Small as it is, it represents a great enterprise. In August of the year 1890 Janssen, the distinguished Paris astronomer, was sent by the Meudon Observatory to ascend Mont Blanc with a view of making meteorological and spectroscopic researches. He started with twenty-two guides, and the necessary equipment, and successfully completed the work. The immediate result simply confirmed the observations made by an expedition two years before. But indirectly the expedition of 1890 also gave the first impulse toward the erection of an observatory on the summit of Mont Blanc. Janssen himself was the originator of the scheme; he secured the interest of several eminent men of France, among them the then president. A committee was formed to transact the business in connection with the enterprise, Janssen being president. As it came to the actual erecting of the building, the little hut of the engineer Vallot, half way up Mont Blanc, was found to be of great value as an intermediate station.

In 1891 a preliminary experiment was made—a wooden hut was built on the site of the finally erected observatory. The experiment succeeded beyond the expectations of the builders, and soon the foundations for the observatory proper were laid. The house was made two stories high, the lower floor being below the surface of the snow, on one hand to make the house more stable, and on the other to obtain a somewhat moderate temperature in the bedrooms on the ground floor. The house was rested on screws, which were let into the snow, and which permitted of leveling it in case the snow should alter its position. This plan was conceived by Janssen, and approved by Vaudremer, the architect of the Academy of Fine Arts, of Paris. The material was conveyed to its destination in eight hundred lots, weighing, together, about thirty thousand pounds. This work was begun in the summer of 1892, and, thanks to the comparatively fine weather that prevailed during its continuation, the construction was completed on September 8, 1893. At seven o'clock in the morning of that day Janssen started from Chamonix to the observatory, where he arrived on the 11th at two o'clock in the afternoon. He took up his work at once, investigating the solar spectrum with regard to the question of the presence of oxygen in the sun.

Our illustration is reproduced from a water color

A LITTLE HUT AT PIERRE POINTUE ON THE WAY TO THE SUMMIT OF MONT BLANC.

PASSAGE DE LA JONCTION, ON THE ASCENT TO MONT BLANC.

painting by Janssen himself. The observatory is situated at a height of 15,682 feet above sea level.

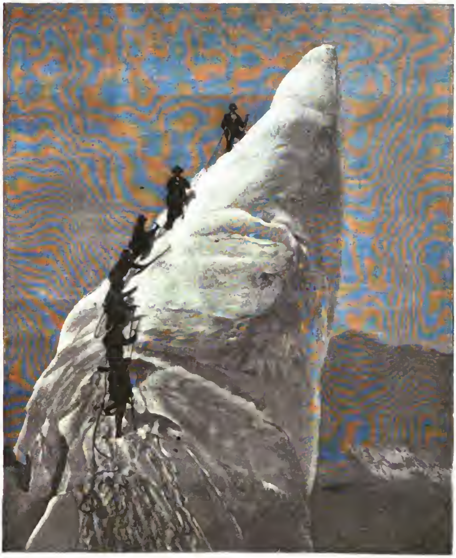
THE ISLAND OF SAKHALIN.*

ALTHOUGH the remoteness of Kamchatka has, to a certain extent, familiarized us with, at any rate, the name of that dreary peninsula, the adjacent island of Sakhalin in the North Pacific Ocean still remains, to the majority of English readers, a sealed book. Of late years, however, its increasing importance as a place of exile for Russian political and criminal offenders has invested Sakhalin with a certain interest, derived, perhaps, more from penal associations than physical resources, which latter may, when fully developed, materially affect trade and commerce in the far East.

The island of Sakhalin is 584 miles in length, its breadth varying from 18 to 94 miles. The southern extremity is separated from the island of Yeso, twenty miles distant, by the Straits of La Perouse, and its western coast by the shallow Gulf of Tartary (at one point barely five miles across) from the mainland of Siberia. Although Dutch explorers are said to have landed here in 1643, the first reliable survey of the island was probably obtained in the year 1787 by La Perouse. Russian fur traders followed in the early part of the present century, but it was only in 1853 that, disturbances having occurred with the natives, a score or so of Cossacks were stationed at Dui, on the west coast. In 1867 negotiations were entered into by the Russian and Japanese governments for joint occupation of Sakhalin, but the subsequent discovery of coal, and consequent influx of Russian convicts, rendered this arrangement highly unsatisfactory. Further negotiations therefore ensued, with the result that, in 1875, the island was formally ceded to Russia, Japan receiving in exchange the entire Kurile Archipelago.

Sakhalin is by no means easy of access. Even during the open season (from May to September) but very few vessels visit the island, and, with the exception of the monthly arrival of convict ships from Europe, and a couple of small Russian trading steamers, there is no fixed service with Vladivostok, which, with the exception of Nikolaefsk, is the only Siberian port whence Sakhalin may in three days be reached. During the winter months the island is completely icebound and unapproachable by water. Communication with the mainland is then maintained by means of dog sledges, and the mails for Europe are dispatched across the frozen Gulf of Tartary—a journey, under favorable circumstances, of about three months. One of the chief disadvantages connected with the island is that it does not at present possess a single harbor worthy of the name. The two principal ports, Alexandrovsky-Post and Korsakovsky-Post, are simply open, unprotected roadsteads, whence on the approach of stormy weather vessels must immediately put to sea. With convict labor, however, and abundance of necessary materials at hand, this should not be a serious difficulty to overcome. It has even been estimated that at Alexandrovsky-Post, on the western coast, a sheltered and secure anchorage could be constructed at a comparatively moderate outlay.

Sakhalin is mountainous, but the ranges, which run chiefly north and south, attain no great altitude, the highest peak, Mount Tiara, being scarcely 5,000 feet above sea level. The island is badly watered, there being only two rivers (the Tym and the Poronai) of any importance, and navigable for small craft for over a hundred miles. More than two-thirds of the island are covered by dense forests, chiefly coniferous, although the elm, poplar and maple are found in some districts, and bamboo is common in the uplands of the south. The climate is very variable. Winter lasts for about one hundred and ninety days, the mean temperature at this season being below freezing point. Spring commences about the middle of April, although, even in May, the thermometer has been known to fall as low as 21° F. Summer is as bright as it is brief, and the average temperature of the center of the island is then 80 to 85° F. The air at this season is mild and delicious, the sky blue and cloudless, and the grassy valleys carpeted with fragrant wild flowers. Some time before his visit the writer had read that* "agriculture and gardening are impossible in the vicinity of Dui," and was, therefore, surprised to find that roses and geraniums flourish in the gardens of Alexandrovsky-Post, barely ten miles from the place in question. The warm season, however, is of very short duration; autumn, with her curtain of clouds and rain, veils the summer sunshine with fatal rapidity, and by the middle of August the island is generally shrouded in dense gray mist. By the end of October the coast is again ice bound, and the whole island covered with snow several feet deep, which seldom entirely disappears until the following May. Notwithstanding these sudden and severe climatic changes, Sakhalin is not unhealthy, and, while prison statistics point to the predominance of rheumatic complaints, epidemics are of rare occurrence, and the death rate is low. Cholera is almost unknown.



SÉRAC ON MONT BLANC.

According to the last census, taken in December, 1891, the settled population of Sakhalin numbered 19,644 souls, of whom 16,416 were Russians and the remainder Gilyaks and Ainos, or aboriginal tribes. The former, who are closely allied to the races inhabiting the banks of the Amur River in Eastern Siberia, lead a precarious existence, dwelling in winter in small settlements along the coast, and in summer leading a nomadic existence hunting and fishing. The Ainos, who originally came from Japan, now inhabit Yeso and the Kurile Islands, and are distinguished from the Gilyaks by their swarthy complexions, long faces and extraordinary hirsute appearance. Both tribes are, on Sakhalin, rapidly dying out. Of wild animals the bear, wolf and lynx are numerous in the forests. The elk is met with in the interior, and sables are caught in the north in considerable quantities, though their skins are of a very inferior quality. Horses and cattle have been imported from Siberia, but, although the former thrive and do well, the latter suffer much from climatic influences, and have as yet proved unsatisfactory. For sleighing purposes, dogs, and occasionally reindeer, are employed.

Sakhalin is, for administrative purposes, divided into three districts, viz., Korsakovsky-Post in the south, Tymovsk in the north, and Alexandrovsky-Post on the western coast. The latter, which is situated in the center of the coal district, is a picturesque, straggling town of about 7,000 inhabitants, consisting almost entirely of officials and convicts. This is the most important penal settlement on the island, contains the largest prison, and is, moreover, the residence of the governor of Sakhalin, a subordinate of the governor-general of Eastern Siberia. Alexandrovsky is garrisoned by about 1,500 men, and contains large foundries and workshops for convict labor, but most of the prisoners are employed in the adjacent coal mines of Dui. The coal is excellent for steaming purposes, but, owing to the difficulties of transport that at present exist, somewhat dear, and it cannot now be delivered for less than 12 rubles per ton at Vladivostok. The output in 1890 was 2,400,000 tons. Korsakovsky-Post, on the south coast, is the next largest settlement, containing about 5,000 convicts who are chiefly employed in agricultural pursuits.* Although it may seem a paradox, the remaining prisons in the interior of the island, Derbynskaya, Rykovskaya and Onor, are not prisons at all, but huge wooden barracks, innocent of bolts and bars. Here, also, the work done is solely agricultural.

Prison life on Sakhalin is undoubtedly harder than on the mainland of Siberia, but, on the other hand, the actual confinement is of much shorter duration.

There are three classes of prisoners, viz.:

(1) Convicts who, having served their time in prison, are free to live in a certain district and earn their own livelihood.

(2) Convicts confined in prison, and compelled to work in the mines, foundries, or at agricultural labor.

(3) Convicts confined to prison in chains.

The latter, of the dangerous class, are naturally kept under strict supervision and subjected to the most severe discipline. An ordinary criminal, however, sentenced to a term of, say, twenty years penal servitude, may by good conduct regain his provisional liberty in a quarter of the time. The state then provides him with a log hut, a plot of land and agricultural implements, and the district to which he is assigned becomes his prison. He is, practically, a free colonist whose wife and family may, if so disposed, join him, a free passage out from Europe being granted them by government. Political exiles are rarely sent to Sakhalin. At the time of the writer's visit there were but three residing at Alexandrovsky-Post.

Many of the better educated men in the first class occupy positions as government clerks, and earn as much as 50 rubles per month. Others find employment as domestic servants, night watchmen, storekeepers, or by working at the trade they have learnt in prison; but the majority prefer to accept the grant of land they are entitled to and take to farming.

Should a convict of the first class attempt to escape, he is immediately replaced in class 2, or, if violent and refractory, relegated to class 3.

The prisons are rough log buildings, cleanly and well ventilated, and the food provided amply sufficient, a convict of even the third class receiving meat four times and fresh fish three times a week. The hospital arrangements are, although primitive, satisfactory, and every prison contains a good school for children of both sexes.

Important changes have taken place of late years in the Siberian exile system, and the conditions under which Russian convicts now travel overland differ essentially from those of even a decade ago. It is now, moreover, probable that the long tramp across Asia will shortly be abolished altogether. All political and criminal offenders will then be transported direct by sea from Odessa (via the Suez Canal) to Sakhalin, and will thus be spared the fatigue and privations that must, even under the most favorable circumstances, attend the journey through Siberia.

Although the two principal towns on Sakhalin are connected by an overland telegraph wire, the interior of Sakhalin is comparatively unknown. Several rough tracks lead from the western coast to inland Gilyak settlements, but these are almost impassable for Europeans. There is only one road of any importance (about fifty miles long) leading from Alexandrovsky to the free convict settlements of Derbynskaya and Rykovskaya.† Here the land has been extensively cultivated, and the contented looking colonists and neat homesteads speak well for the Sakhalin prison administration. Of the 20,000 acres of cultivated land on the island, nearly half is clustered around these pretty villages, where corn and vegetables are grown in large quantities, while hay is actually exported to Japan. It is said that the most fertile districts have not yet been opened up, and that the soil south of this point is even more favorable to the production of cereals.

Game and wildfowl are scarce in Sakhalin, but its rivers teem with fish of all kinds, while, off the coasts, cod, salmon and herring abound. The codfish are nearly all sun dried and exported for food, but the bulk of the two latter are converted into manure for Japanese tea and paddy plantations, and fetch from £8

* From the Fortnightly Review.

* In Russian and French Prisons. By Prince Kropotkine. Ward & Downey, London.

* Of the 5,000 convicts at Korsakovsky-Post, only 1,500 are actually confined in prison.

† This road has now been carried on a distance of about twenty-five miles to Onor.

to £9 per ton. The largest and most important fishery on Sakhalin is owned by Mr. Denbigh, an old King's College man, who also trades extensively in seal and sable skins; but as fish manure is apparently, in his case, the most profitable article of commerce, the methods employed in catching and preparing the fish for exportation to Japan are perhaps worthy of notice.

At stated seasons of the year the herrings visit the coast in shoals for the purpose of depositing their roe, the first run usually occurring about the beginning of May, and being followed at intervals by others till the middle of June, when the fish disappear until the following spring.

A large trade is also done at Mauka in the long ribbonlike pieces of seaweed that, in the Gulf of Tartary, often cover the surface of the sea for miles. This is gathered, dried and shipped to China, where it fetches a good price and is considered a great delicacy.

Notwithstanding its climatic disadvantages, Sakhalin possesses so many resources that their development can only be a question of time. The Russians are a proverbially dilatory people; but there can be little doubt that the increase of population and enterprise, consequent upon the total abolition of Siberian exile, will within the next few years bring this lonely island, of which so few of us have even heard the name, into prominence and perhaps renown. Harry de Windt.

PORTABLE LUMINOUS PROJECTOR.

The curious property that platinum possesses of remaining incandescent for some time under the influence of hydrocarburets has long been known. This is an experiment that has been made in all courses of lectures since the time of Davy. It suffices to raise a fine platinum wire to a red heat, and then to place it over a saucer containing benzine, in order to have it remain incandescent. It is only within the last twenty years that advantage has been taken of this property in surgery, with the instruments devised by Dr. Paquelin and known as thermo-cauters. As long ago as 1857, M. Mathieu, at the suggestion of M. Masson, professor of physics at Louis-le Grand, constructed a surgical cauter based upon this principle; but it was not very successful, probably on account of defects in its manufacture. The wide use now made of the Paquelin apparatus proves that surgery has found therein a valuable auxiliary, and it is surprising that more of an endeavor was not formerly made to utilize those of Messrs. Masson and Mathieu.

In another order of ideas, Mr. Brenot, a skillful manufacturer of surgical instruments, who has for several years been constructing cauters of iridescent platinum, has recently utilized this same property of platinum for making illuminating apparatus. The idea was suggested to him by Dr. Mareschal, the principal surgeon of the army, who, in his Tonkin and Madagascar campaigns, often had occasion to regret the absence of an intense light in the arrangement of ambulances.

The idea of utilizing platinum kept incandescent under the influence of hydrocarburets for illumination is not new, since, in 1875, M. Lodi-Montaigne took out a patent on this subject, although his apparatus was no more successful than the Masson-Mathieu cauter, and probably for the same reason. It does not, in fact, suffice to start from a known principle; it is necessary also to seek a sure method of obtaining a maximum of the effect to be produced. In order to keep platinum incandescent for a long time and at will, it is necessary to fulfill certain conditions that have been particularly studied in the apparatus that are daily operated by surgeons. The hydrocarburet generally employed is what is called gasoline. By means of a blowing apparatus, there is set up a current of air and gasoline vapor which must be mixed in certain proportions in order to give the maximum effect. A special two-way cock permits, in the Brenot apparatus, of finding, after a few tentatives, the exact point at which the mixture is made under the best conditions.

The illuminating apparatus in itself is very simple. It consists of a small sphere of platinum gauze (Fig. 1, No. 1), of a size dependent upon the purpose for which the apparatus is intended, placed in the center of a metallic reflector. The handle that supports the whole is hollow and filled with a sponge saturated with gasoline. At its lower part there is a regulating cock which connects it with the blowing apparatus. The latter may be of variable form, but, as a general thing, there is employed a rubber bulb which is actuated either with the hand or with the foot, when, as in the projector designed to illuminate the larynx (Fig. 1, No. 2), the two hands are occupied. In the experiments recently made at Vincennes, there was employed with advantage air compressed in reservoirs carried upon the back and in which the supply of air was easily renewed by means of a small pump forming a part of the reservoir. These apparatus are found in the market, and are used for spraying grape vines. As the apparatus is not bulky, is very portable and is quickly set in operation, it is possible to produce an intense light at once in any place and in a determinate direction. With a projector having a reflector 0·24 m. in diameter, a surface of 40 square meters is illuminated at a distance of 200 meters, and the luminous intensity is sufficient to allow a person easily to read a newspaper at a distance of 100 meters. An illumination such as this will be a valuable aid in many military operations such as harnessing horses to batteries, lighting roads, engineering work, searching for wounded, urgent surgical operations, etc. From another view point in ordinary life also the Brenot projector will render many services, and we would especially mention the use of it for the search of malefactors and poachers (Fig. 2). It will perhaps be possible to apply it to the lighting of automobile carriages and bicycles.

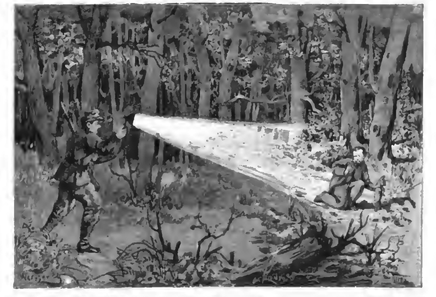


Fig. 2.—POACHER SURPRISED AT NIGHT BY MEANS OF THE PORTABLE PROJECTOR.

For the latter, the simplest arrangement would be to carry a reservoir of compressed air and keep the pressure up by pumping from time to time by hand. But for automobile carriages it would be very easy to arrange a pump that could at will be connected with the motor or even be set in operation automatically when the pressure of the reservoir reached a point regulated in advance.

These are projects that we propose to those whom it may interest, the inventor of the pump not having the time to study it himself.—La Nature.

THE HALF TONE PROCESS POPULARLY EXPLAINED.*

By W. Gamble.

Having undertaken to popularly explain to you the half tone process, I ought, perhaps, in the first place, to make it clear to you what is meant by the term in its relation to process work. I have heard it stated that the process is called half tone because in the reproduction the picture is lowered to a half tone—that is to say, possessing neither high lights nor deep shadows. That explanation is, however, a mistake. The term "half tone" came about in this way. The difficulty of the early process workers was to find a satisfactory method of reproducing the half tones of the photograph in surfaces for mechanical printing. Taking the case of typographic blocks, it was easy to reproduce high lights by leaving the printing block hollow in those parts, so that they would not be covered with ink, and would deposit no color on white paper. It was also easy to reproduce shadows by leaving those parts in relief on the block so that the ink was deposited on them, and thus transferred a patch of solid color to white paper. But what would become of the half tones? It was not possible by the operation of passing a roller over the block to lay half a shade of ink on certain parts. Thus it was a picture without half tones, and therefore merely a silhouette. But these early process workers were led to reflect that the wood engraver got his tones by means of lines of more or less thickness, and by placing lines closer or further apart; also that the aquatint etcher obtained his effects by varying openness of a resinous grain, while the mezzotinter and the steel plate engraver obtained their effects by the closeness and size of the stippling; and, again, the lithographer took advantage of the grain of a coarsely ground stone. Thus it was argued that if the half tone of a photograph could be broken up into some sort of a grain, the problem of making the photograph into a printing block would be solved. We know that this problem was solved, after years of patient experiment, by placing in front of the sensitive plate a ruled screen—that is to say, a network composed of crossed lines on glass.

The photographic image was thereby broken up into a grain, which reproduced the tones of the photograph by dots of varying size. Half tone reproduction was, accordingly, achieved; and, naturally, the method was called the half tone process. I do not know who first called it "half tone," but probably it arose in this way:

It was variously called by different workers according to their fancy; for instance, it was the "Meisenbach" process, so called after the patentee of one of the methods, while others called it the "nature" process; and, besides, there arose such names as "heliotype" and "luxotype."

But the public wanted to know what these strange terms meant; hence it was usual to add "a process for reproducing the half tones of photographs," and this soon became shortened into "the half tone process." So this name, ugly as it is, has stuck to the business.

Now let us see how this half tone process is worked.

The first and most important requirement is a screen. This consists of two pieces of plate glass cemented together, and on the inner sides of these two plates are ruled parallel black lines, the lines on the one plate crossing those on the other so as to form a network. The most perfect screens are those made by Levy, of Philadelphia.

His method of manufacture consists in coating the glass with a ground which will resist a glass etching mordant, cutting the lines through the film by a diamond point driven by a dividing engine, and then etching the glass left bare. The resulting furrows are filled in with an opaque pigment, and the screen thus formed is very perfect in the two essential qualities of opacity and transparency. These screens are ruled in various degrees of fineness or coarseness, the ruling determining the size of the grain points. Thus for poster work fifty-five lines per inch are used. For newspaper blocks to suit rough and rapid printing seventy-five or eighty-five lines are used. Various styles of printing are accommodated with rulings between 100 to 175 lines to the inch. It is possible to get screens of 200 to 240 lines to the inch, but the blocks from these are a bit too fine for British printers. Most of the half tone work you see about in the magazines and illustrated papers is done with screens of about 120 to 150 lines to the inch. It is to be noted that the finer the screen used, the greater the amount of detail; the coarser the screen, the greater the amount of contrast.

The screen is placed in the camera immediately in front of the sensitive plate, but not in contact with it. In fact, provision must be made for securing a variable distance between the screen and sensitive plate, for

* Paper read before the Photographic Convention of Great Britain, at Yarmouth, July, 1897.

reasons which I will presently explain. In cameras made specially for half tone work there is in the back of the camera a screen carrier, which is made to travel to and fro by means of a lever or screw, and the distance at any point is shown by an indicator on the outside of the camera. When the dark slide is inserted and the shutter drawn, the screen carrier is brought forward as near to the plate as may be required. In the same way the screen may be brought up to the focusing screen until the right effect is observed, when the distance shown by the indicator is noted, and the screen can be set again to this distance when the dark slide is put in.

The old fashioned way of using the screen was in the dark slide, having two carriers—one for the plate remaining fixed and the other for the screen being separated to varying distances by means of strips of cardboard. It was a clumsy method, and I have here a newly invented slide in which there is a mechanical screen adjustment from the outside, and there is an indicator plate to show the distance. It forms a very compact arrangement, and its great merit is that it can be attached to any camera, so that if any of you want to dabble a bit in the half tone process you can fit up even a half plate camera with this slide.

The lens used for the process may be any good rapid rectilinear, but it must have a slot for Waterhouse diaphragms, not an iris, because it is necessary to vary the shape of the diaphragm openings. It is further necessary that the lens be fitted with a prism or mirror for reversing the negative, otherwise, as we print from the negative direct onto the block, we shall get a block which will yield an ultimate print the wrong way about.

The remaining fit up is pretty much in accordance with the ordinary arrangements for copying.

Having told you about the apparatus used, I must next explain to you the principles involved in the making of a half tone negative.

You want to know why it is necessary to place the screen at a certain distance, and how that distance is arrived at. Also why it is necessary to vary the shape of the diaphragm, and what is the shape required.

First, as to the screen distance. The early workers thought that the screen had merely a "chopping up" effect on the picture. The result of this want of knowledge was that the operator simply placed the screen close to the sensitive plate, and aimed at making it cast a sharp shadow of its lines on to the plate. The result was that the early half tone work had a raspy, gauze-like effect, which entirely killed all the delicate tone and detail of the picture, and even to this day some work has this characteristic as a result of the imperfect knowledge or perversity of the operator, who is much inclined to cling to obsolete methods of working. It was not till operators began to understand that the screen was an optical instrument, and not simply a sieve, that half tone work began to improve. Investigation into the theory of the screen working showed that under suitable conditions the screen might be regarded as a collection of tiny apertures which acted the part of pinhole lenses. It was just like the battery of "gem" lenses that you are familiar with for making postage stamp portraits, except that each aperture, instead of making a separate picture of the object, could only photograph the illuminated spot of light at the diaphragm opening.

Thus you will understand that there was a double action going on, viz., that while the picture was photographed through the screen by means of a lens, every aperture of the screen was doing a little business on its own account, namely, it was photographing the shape of the spot of light at the diaphragm opening. Of course, if the apertures of the screen were acting as pinhole lenses, they required a working focus; hence a screen distance was necessary.

Now, you will say, "We quite understand that this pinhole action may go on, but what is the use of it?" To explain it I must go forward a little to the printing process.

What we require in a half tone negative is a means of printing the picture on to the zinc or other metal plate in dots of varying size—big dots for black shadows, medium dots for half tones, and fine dots for high lights. Now if we are to print dots, we must have a negative, punctured, so to speak, with holes, but it is certain that if the lines of the screen were in contact with the plate we should not have a "perforated" negative, but the exact opposite, viz., a negative of separate dots, just as if you take a print from a piece of perforated zinc on to sensitive paper. But suppose you put the screen a little distance away and allow the pinhole action to form a larger dot, you can understand that it is possible to carry this spreading action until each dot touches and even overlaps its neighbor. Well, then, as the dots group themselves in spaces alternately, like the black squares of a chessboard, you will see that by making them spread until they touch, we get the "perforated" negative we require. In the old way, by assuming that the only object of the screen was to cast a shadow, the spreading of the dot had to be forced by long exposure and by vigorous intensification, which made the negatives hard and screeny, but by taking advantage of the pinhole action, the spreading is accomplished in a quick, harmonious and natural way. Another important advantage is gained. We find that the further the screen is from the sensitive plate, the less is its effect in breaking up the picture, and this also holds good to the extent that, if the screen is far enough away, the negative shows no screen effect at all; you would not know the screen had been there. Thus, you see that by taking advantage of the pinhole action, we can work our screen a considerable distance from the plate, and we get thereby more tone and detail. That explains the wide difference between the half tone work of to-day and that of even two or three years ago. The improvement is due to operators having found out, consciously or unconsciously, this little secret of the working of the screen.

The altering of the shape of the diaphragm had the same object in view, viz., the spreading of the dot in a suitable direction, so that we may get the "perforated" negative I have described. As the dot is formed by pinhole action, it is obvious we can make the dot any shape we please by altering the shape of the diaphragms. Thus we find that square dots give a better joining up to each other than round ones.

Once the operator has grasped these leading principles of the process, the negative making is an ordinary photographic operation, and either wet plates or dry plates may be used. There always has been a great prejudice in favor of wet plates, but for my own part, I find just as good, if not better, results can be obtained on suitable photo-mechanical dry plates.

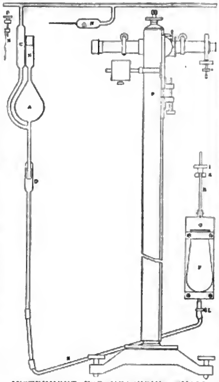
The negative made, it is printed on to a zinc or copper plate sensitized with a bichromated film, generally of albumen, gelatine, gum, or fish glue, the latter being now perhaps most extensively used.

The process is analogous to carbon, the film, after being exposed under the negative, being developed by washing away the parts which have been protected from the light.

The development is continued until the zinc is laid bare between the dots. Then the plate is dried, and in the case of fish glue, is heated until the glue is made so hard as to be acid resisting. Then the plate can be etched until the dots stand in sufficient relief to yield a printing surface. The remaining operations are only those of fitting it for the typographic printing press by trimming up and mounting it to the height of type.

Now I hope I have made plain to you what this half tone process is, and I want to plead with you to give it a little more tolerance. It is not yet perfect, but it is a young process and will improve. One so often hears tirades against it, and it is often said that "process" is antagonistic to the interests of the photographer on the one hand and the artist on the other. I do not believe any such thing. On the contrary, it has widened the scope of photography and opened a more extensive field for the artist. Where photography was only a method of producing portraits and views ten years or less ago, it now takes rank as one of the graphic arts. In this year we have been summing up on every hand the advantages we have gained from the prolific inventions of the present reign, but I think it has been overlooked how much has been done to three industries which have arisen out of the processes invented and brought to perfection in what has been called the Victorian age. I refer to electrotyping, stereotyping (by the papier maché process), and photo-engraving.

Take away these valuable auxiliaries of the printer, and we deprive at once the masses of the people of their cheap literature, whether it be in the form of books, newspapers or magazines. Pictorial knowledge is the most easily imparted, and has played a large part in the literature of this reign; indeed, we cannot measure how great a debt this age owes to photography and the photo-mechanical processes by reason of the wealth of illustrations which they have provided—not simply pictures that amuse, but illustrations which have made scientific, technical and general educational works far more valuable and instructive.



INSTRUMENT FOR MEASURING SMALL GASEOUS PRESSURES.

THE MEASUREMENT OF SMALL GASEOUS PRESSURES.*

By CHARLES F. BRUSH.

PRIOR to the invention of the McLeod vacuum gage, the measurement of even moderately small gaseous pressures was difficult, and subject to large errors. The introduction of the McLeod gage, however, early in the seventies, seemed to solve the problem. In its ordinary form, and for most purposes, this beautiful instrument admirably serves the purpose for which it is designed. But when very accurate measurements of pressures as small as a few millionths only of atmospheric pressure are desired, its performance is extremely unsatisfactory and vexatious. As is well known, the chief cause of the difficulty is the unequal and variable capillary depression of the two small columns of mercury, whose difference in height indirectly serves as the measure of pressure. Accurate measurement of this capricious difference obviously avails nothing.

Three or four years ago I was engaged in an investigation requiring frequent and simultaneous measurements of slight but different pressures in two large glass globes connected by a capillary tube. For this purpose I constructed and carefully calibrated two large McLeod gages. The internal diameter of the mercury tubes was about three millimeters, and they were made from contiguous parts of the same glass tube selected for uniformity of bore. These gages were often compared by measuring the same vacuum with both; but they rarely gave concordant results. Indeed, it was not uncommon at high exhaustions for one or the other of them to indicate a negative vacuum; that is to say, less than no pressure at all. The case of these two gages is cited because of the opportunity they afforded for comparison. In prior work I had, like most experimentalists, used but one gage; and while always suspicious of its indications, had no means of knowing how large its errors might be.

The phenomenon which I next desired to investigate is the spontaneous evolution of gas from glass and other surfaces in high vacua. For this purpose an accurate and entirely reliable means for measuring very small pressures was necessary, because I could not afford to wait months or years for the evolution of sufficient gas to be detected with certainty by the old gages. To meet these requirements I designed, constructed and learned how to use the modified form of McLeod gage which it is the purpose of this paper to discuss. It was deemed necessary to provide an apparatus capable of easy use, and giving results having a probable error not greater than a fiftieth part of a millionth of atmospheric pressure. My hopes of attaining this high ideal were far more than realized, as the sequel will show. Instead of having to wait days or weeks in the course of my investigations for the evolution of a measurable quantity of gas, as had been expected, the progress of evolution could be noted from hour to hour; and the increase in the rate of evolution due to a rise of one degree in the temperature of the laboratory was unmistakable.

The diagram herewith shows the essential parts of my apparatus. The bulb, A, of the gage, is made conical in its upper part, to avoid adhesion of gas bubbles when the mercury rises. This bulb holds about eleven pounds of mercury. B and C are the gage head and comparison tube respectively. They are nearly twenty millimeters inside diameter, and are made from contiguous parts of the same carefully selected tube. D is the usual air trap, and E is a long glass tube, with flexible pure rubber connections to the lower end of the gage stem and the mercury cistern, F. The latter is mounted on a carriage, G, which moves vertically on fixed guides. The height of the carriage is adjustable, at the upper end of its range of motion, by means of the screw, H, thumb nut, I, and forked support, K. The screw is pivoted to the carriage, so that it may swing out of the fork when the carriage is lowered. L is a pinch cock with screw, for regulating the flow of mercury, or stopping it altogether, while pumping out the trap, D. N is a bulb containing phosphorus pentoxide, to keep the interior of the gage and other parts of the apparatus perfectly dry. P is a very elaborate cathetometer for observing the mercury columns in B and C. This beautiful instrument has a revolving column with vertical scale, and vernier with microscope, reading to hundredths of a millimeter. The eyepiece micrometer reads directly to hundredths of a millimeter, and the divisions on the revolving head of the screw are so open that tenths of divisions are easily and certainly estimated by an experienced eye; thus permitting the micrometer to be read directly to thousandths of a millimeter. Of course the cathetometer is permanently located, not as shown, but with the objective of its telescope equally distant from the axes of the tubes, B and C, when it is alternately directed to them; and at such a distance that its micrometer readings correspond to a millimeter scale. The whole apparatus is located in a basement room, on a stone floor, whereby vibrations are reduced to a minimum.

The most important part of the gage is the head, B. The purpose of its great diameter is the reduction of capillary depression in its mercury column. But its size necessitates a very close approach of the mercury to its upper end, in order to sufficiently reduce its capacity. Yet the remaining space must be measurable by the cathetometer with the utmost precision. Hence the glass must not be distorted by heating, and the closed end just over the mercury must be sharply defined. In constructing this part of the apparatus, I selected a piece of heavy tubing which would just slip inside of B, with the least possible clearance. One end of this tube was closed as squarely as possible by fusion, and then ground with fine emery and a suitable tool to a convex spherical surface of long radius. Care was taken to make the center of curvature lie in the axis of the tube, and the ground surface was left unpolished to facilitate observation. A suitable length of the closed end of the tube was then cut off, slipped into B, and both tubes were fused together at their open ends as shown.

For calibrating the head, B, a ground glass stopper with a capillary duct was fitted to its neck, before the latter was sealed to the bulb, A. The head was then filled with mercury by boiling, thus completely filling the small space between its wall and the cap. After cooling, the stopper was inserted to expel all excess of mercury, and the whole weighed. Next the head was emptied and the mercury in the annular space distilled out. Again the head was very nearly filled with mercury, without allowing any to get into the annular space, and weighed as before; and the space between the top of the mercury and the convex end of the head was very carefully measured by the cathetometer. This process of weighing and measuring was repeated several times, with less mercury each time. Thus the capacity of a vertical millimeter of the head was ascertained, as well as the capacity that would remain, if the top of the meniscus of mercury just touched the convex end of the gage above it. Finally the neck was sealed to the bulb, A, and the capacity of head, neck and bulb combined was found by weighing them empty, and again filled with mercury.

For lighting the top of each mercury column, a narrow horizontal slit in an opaque screen, R, is used. The slit is covered with a strip of ground glass, and oblique-

* Read before the American Association for the Advancement of Science, August 28, 1897.

ly illuminated by an electric lamp. The screen and slit are vertically adjusted by a thumb screw, S. The heat of the lamp is prevented from reaching the mercury columns and head, B, by a thick screen. This is very necessary.

In order to get the best results from the apparatus many precautions are necessary. After filling A and B with mercury, time must be allowed for the compressed gas to cool. The effect of changing barometric pressure is nearly eliminated by so regulating the quantity of mercury in F that its surface is in the small tube at the bottom of the cistern when the gage is properly filled. Its area is then very small, as compared with that in B and C. The height of the menisens in both tubes is easily adjusted sensibly equal, by a little manipulation. I always raise the mercury above the point at which readings are to be taken, and then lower it, so as to read on a falling meniscus. This is highly important.

Some trouble was occasionally experienced at first from electrostatic induction between the mercury in B and the glass above it. This was shown by distortion of the meniscus when it was brought very near the glass. The difficulty was partially, but not wholly, remedied, by putting mercury in the outside open end of the gage head and connecting it by a flexible conductor with the mercury in the cistern, F. A complete remedy was effected by moistening the inside of the gage head with a dilute solution of phosphorus pentoxide. This became completely dried by the anhydrous phosphorus pentoxide in N, but was, of course, not dehydrated; and hence always remains conducting, and dissipates the static charge.

Large pressures, up to a thousand millionths or more, are readily measured with this apparatus, by finding with the cathetometer the distance between the mercury in B and the end of the head above it; from this is quickly calculated the necessary multiplier for the number of millimeters difference in height between the columns in B and C, also measured by the cathetometer, in order to express the result in millionths. For very small pressures, the micrometer wires are set at such a distance apart as to give a convenient constant (usually 2); and the column in B is adjusted this distance away from the glass; careful allowance being made for the thickness of the wires. Then the micrometer is used for repeated measurements of the difference in height of the mercury in B and C. The disturbing effect of bias is entirely eliminated by giving the micrometer screw a partial turn after each reading. Thus the next measurement is made without any knowledge of its difference from the preceding one, until the eye is removed from the telescope.

In my early experience with the apparatus, unusually careful measurements of very small pressures were often made, to determine how far its indications might be relied upon. In this connection I quote as follows from my notes, under date of February 20, 1895, concerning the last one of the series of pressure determinations: "Following is the last reading in detail, showing the extreme accuracy of these measurements:

	M.	M.	M.
	0·432	0·438	0·441
	0·441	0·4335	0·429
	0·4385	0·4275	0·4305
	0·426	0·450	0·445
	0·4335	0·4425	0·432
	0·4395	0·432	0·4185
	0·4305	0·435	0·435
	0·441	0·432	0·453
	0·435	0·4215	0·4425
	0·435	0·4245	0·438
Means...	0·4347	0·43365	0·43545

Mean of all the readings, 0·4346 M.

"Readjusted zero point of micrometer before each reading of each set. Partially emptied gage and readjusted capillary depression before each set of readings. The first series has no known source of error. The second and third series were made during wind squall, and surface of mercury was often tremulous. In the third series, capillary depression was perceptibly, though very slightly, unequal, in direction to make readings too high."

In the above quotation "M" means millionths of atmospheric pressure. The calculated probable error of the thirty readings taken together is only ninety-two hundredths of a unit in the third decimal place; that is to say, less than a thousandth part of a millionth of atmospheric pressure! The probable error of the three mean results, considered as single readings, is only eleven hundredths of a unit in the third decimal place of millionths. The net result may be expressed as follows, in terms of atmospheric pressure. Considered as thirty measurements:

0·000 000 434 60 ± 0·000 000 000 92.

Considered as three measurements:

0·000 000 434 60 ± 0·000 000 000 11.

Here we have the measurement of a total quantity of less than half a millionth of atmospheric pressure, with a probable error of only about a fifth of one per cent. of the quantity measured.

To show how small is the effect of variable capillary depression in the large mercury columns, the following measurements were made July 23, 1897. No correction was made of accidental capillary differences, but the columns were always observed with a falling meniscus. The zero of the micrometer was freshly adjusted for each reading; and before each of the six sets of readings the mercury was lowered, and then readjusted to the proper height in the gage head.

	M.	M.	M.	M.	M.	M.
	2·210	2·208	2·200	2·198	2·198	2·202
	0·204	0·195	0·202	0·203	0·204	0·198
	0·209	0·198	0·204	0·208	0·209	0·196
	0·203	0·204	0·210	0·209	0·196	0·208
	0·203	0·192	0·202	0·198	0·196	0·203
Means	2·2058	2·1984	2·2054	2·2014	2·1988	2·2014

Calculating the probable errors we have:

Six mean readings .... 2·20187 M. ± 0·00078 M.
All readings ... . 2·20187 " ± 0·00069 "

The effect of not equalizing the capillary depression is very apparent when these results are compared with the earlier ones quoted. But, on account of increased skillfulness of observation, due to long experience, the individual readings of each set are more uniform than before; so that the net result is better.

In this example we have the measurement of about two millionths of atmospheric pressure, with a probable error of only one part in three thousand of the quantity measured.

From the foregoing we may safely conclude that, with the apparatus described, small gaseous pressures may be easily measured, with a probable error of less than a thousandth part of a millionth of atmospheric pressure.

The smallness of this fraction is difficult to realize. It is comparable with a thousandth part of a milligramme in a thousand grammes; or a single kernel of wheat in two thousand bushels; or an inch and a half in the circumference of the earth; or the thickness of a sheet of tissue paper in sixteen miles.

RAREFIED AND CONDENSED AIR.*

AFTER reading Paul Guessfeldt's enthusiastic description of "mountain ecstasy," as he calls it, which the rarefied air of high altitudes produces and which he describes as consisting of "an increased sense of joy caused by an increased muscular activity, and a wonderful buoyancy of the feelings which at moments rises to ecstasy," we are tempted to follow him to those heights in order to experience these feelings which can be so easily obtained with a little physical exertion.

A different point of view is presented to us by D'Orbigny (1826) in an account of the sensations he experienced while crossing the highest pass of the Cordillera in Bolivia, which is 4,500 meters (about 15,600 ft.) high, on his way from the coast of Peru to La Paz. For several days before reaching the highest part respiration was difficult. His driver, the mule he was riding and his dog suffered so much that they were compelled to halt every 20 or 30 meters to regain their breath. While crossing the crest of the ridge he suffered intensely from pains in the temples, vertigo and extreme difficulty in breathing. Every movement of the body produced palpitation of the heart, followed by a feeling of general debility, until bleeding of the nose finally relieved him. During this attack of "mountain sickness" he saw two natives, who had overtaken him, hurry on their way, climbing the rocks with the greatest ease.

It is evident that D'Orbigny did not belong to an Alpine club, and did not have the necessary training, or else he would not have suffered so intensely at an altitude which has no effect upon those who now ascend Mont Blanc.

A man who has no practice in mountain climbing is apt to experience sensations similar to those which D'Orbigny described, while yet under the ordinary atmospheric pressure. For instance, in hurrying up a steep incline, say in the winter, when you sink into the snow with every step, you will very likely become short of breath, since the rapid climb prevents the full expansion of the lungs. This disturbs the circulation of the blood, which, being no longer freely admitted into the contracted lungs, collects in the veins. They swell up, the face becomes purple, the pulse beats are accelerated, and palpitation of the heart sets in. In case the exertion is continued, an attack of nausea is imminent, together with a feeling of faintness in the lower limbs, as the overworked muscles are deprived of their requisite supply of oxygen. A few long-drawn breaths usually suffice to remedy the disorder. By gradually becoming accustomed to walking and breathing slowly and regularly a further attack is prevented.

These symptoms, as they manifest themselves in the rarefied air of high altitudes, constitute what is known as mountain sickness, and persons unaccustomed to mountain climbing are frequently affected by it even while resting or when not exerting themselves. Here, again, the cause of the disorder is the insufficient expansion of the lungs, caused by the diminished atmospheric pressure, which renders respiration difficult.

But it may be objected that the energy with which we inhale the air is the same at high altitudes as below, and the rarefied air ought to penetrate into the lungs more easily. This is perhaps true, but, although we expand the chest during inhalation, the expansion of the lungs is only accomplished by means of the atmospheric pressure. The lungs are not attached to the inner surfaces of the thorax and can move freely. A wound in the thorax which admits the passage of air causes the lungs to contract, and all the exertions of the breathing apparatus will be powerless toward relieving this contraction.

As long, however, as the cavity of the chest remains closed and contains no air, the pressure of the air in the lungs acts from within outwardly, and by expanding the lungs will cause them to remain in contact with the sides of the chest as it expands during the process of inhalation. The ease with which the lungs are expanded depends upon the amount of atmospheric pressure which is brought to bear upon their elastic power of resistance, and this action consequently becomes more difficult as the lighter pressure of higher altitudes is reached. Let us suppose that the usual pressure is reduced to one-half, then the rapidity with which the lungs are expanded, although still greater than the usual rate of the chest expansion, is yet only half as rapid as when under the customary atmospheric pressure, and under certain circumstances this may seriously disturb inhalation.

Exhalation, on the contrary, is accelerated by the lighter pressure of a rarefied atmosphere. It generally takes place without the aid of the muscles which assist in the process of inhalation. The expanded parts, as the lungs, diaphragm, etc., contract to their original size and position by reason of their elasticity, as soon as the muscular force which was applied during inhalation is relaxed. The employment of the abdominal and intercostal muscles as an aid to exhalation is exceptional.

The only obstacle which retards the contraction of the lungs is the pressure of the outer air, which resists the outflow of the air from the windpipe and is diminished as the atmosphere becomes rarefied. Consequently the contraction of the lungs is greater and more rapid in a rarefied atmosphere. Exhalation is, therefore, in general, a mechanical process, and as such is subject to a certain law according to which it can be performed on the summit of Mont Blanc in $\frac{7}{8}$ of the time required under the ordinary atmospheric pressure.

Humboldt tells us that newcomers in the vicinity of Quito, Ecuador, where the altitude is between 2,600 and 3,600 meters (11,800 ft.), have considerable difficulty in breathing, especially when talking rapidly. This is explained by the fact that the supply of breath usually reserved for the formation of sound escapes more rapidly and is therefore sooner expended. It has also been observed that some persons are unable to whistle where the pressure has only been diminished from 760 mm. (ordinary atmospheric pressure) to 500 mm. The whistling sound is produced by placing the lips in a certain position, and depends upon the rapidity with which the air is forced out of the lungs by means of the abdominal muscles. Naturally, the amount of muscular force so expended is still suited to the requirements of the denser air to which one has been accustomed. As the atmospheric pressure is diminished, the air escapes more rapidly and the expected sound is not formed. In order to learn again how to whistle, it is necessary to place the lips in another position and to apply the muscular force differently, which always requires considerable time and practice.

Physicians who have made a short stay at Davos, which lies at an altitude of only 1,600 meters (5,200 ft.), state that during that time their respiration was much accelerated, while there was an inability to breathe deeply. The explanation of this phenomenon is the diminished atmospheric pressure, which also causes an acceleration of the pulse beats—the inevitable result of insufficient lung expansion. Accelerated breathing at high altitudes affects metabolism by aiding in the removal of gaseous excretions, such as carbon dioxide.

Aeronauts observe the acceleration of the pulse to be the first physiological change. They can reach a much higher altitude than mountain climbers without having any difficulty in sustaining respiration, as their muscular exertion is not so great. But the transition to the rarefied air is more sudden, and the increased difficulty in breathing, which now appears, although the aeronaut is generally unconscious of it at first, results from an insufficient expansion of the respiratory organs, which renders them incapable of admitting the requisite amount of rarefied oxygen. The strength of his respiratory muscles is diminished; he finally loses control of his limbs and his senses are dulled. This was the experience of Croce Spinelli, Sivel and Tissandier, who, on August 15, 1875, reached an altitude of 7,000 m. (23,730 ft.), with an atmospheric pressure of only 300 mm. in two hours. They followed Paul Bert's advice and inhaled oxygenated air, as a result of which their strength immediately revived.

After a long sojourn in regions of high altitude the symptoms of mountain sickness pass away, as respiration is gradually regulated to suit the conditions of the rarefied atmosphere. The change which this necessitates is easily explained. In order to breathe deeply it is necessary to expand the lungs more slowly, and this is only accomplished by means of continuous unconscious practice, which strengthens the respiratory muscles. The members of Alpine clubs who make high ascents keep in practice by repeating their excursions frequently. Hence they are far less subject to mountain sickness than those who have had no previous training.

The wonderful feats of Paul Guessfeldt, which are described in the German Rundschau of 1892, are a good illustration of the benefits to be derived from such a training. He breathed and moved without any inconvenience at an altitude of about 5,500 meters, where the atmospheric pressure is equal to only one-half of the ordinary pressure. In ascending Mount Aconcagua, in Chile, he had no difficulty in breathing until after the altitude of 6,000 meters had been reached, and even then he was finally able to ascend to the summit, which has an elevation of nearly 7,000 meters, or 23,910 ft., an altitude at which aeronauts are compelled to have recourse to their supply of oxygenated air.

A distinguishing characteristic of the air of high altitudes as compared with that of lower regions is its freedom from moisture. The atmosphere is so dry on the plateaus of the Andes in Peru and Bolivia, where the altitude ranges from 3,600 to 3,900 meters, that the flesh of butchered cattle can be dried in the open air. The two explorers D'Orbigny and Wedell both report that the sheep which are killed there are split open and salted, after which they are hung up in the open air and are dried in four or six days.

The ocean is the chief source of the moisture contained in the atmosphere; consequently, the interior of the continents is drier than the coast regions, and in the same way the moisture decreases as we rise above sea level. The lower stratum of air up to about 2,000 meters (6,500 ft.) contains one-half of the whole amount of aqueous vapor in the atmosphere, and here the cloud formations are densest and most frequent, while above this altitude the sky is much clearer.

It is a well-known fact that extreme dryness of the atmosphere stimulates the nervous system, making one feel brighter and more inclined for both physical and mental activity. The inhabitants of very dry regions, according to the reports of explorers, are free from any tendency to obesity.

In trying to escape from the hot air of the cities in the summer we look for a place which is situated higher above sea level, because we know it to be cooler. In the torrid zone, resorts with an elevation of from 2,000 to 3,000 meters are popular. In spite of being nearer to the sun, the air is cooler, as the sun's rays have practically no effect upon it. The air allows the rays to pass through it freely, but receives its warmth from the dark heat rays which are reflected from the earth after the sun has warmed it. The lower strata of air are, therefore, always warmer than the upper. But the plateaus of the highlands are cooler too, as well as the summits and crests, for their rarefied atmosphere is incapable of absorbing as much of the heat reflected by the earth as the denser atmosphere of the lowlands. Although the surface of the earth receives more heat at high elevations, it is immediately reflected back into space without heating the air to a corresponding degree. This is evidenced by the fact that at high altitudes the difference of the temperature in the sun and in the shade is greater than in the lowlands. But the effect of the sun's rays is felt more keenly at a

* From Science.

high elevation, so much so that persons staying at Davos can enjoy a sun bath in a sheltered spot even in the cold of winter, although wearing much thinner clothing than at home.

It takes a visitor at Cerro de Pasco, in Peru, which lies at an elevation of 4,300 meters, 10 or 12 days to thoroughly regulate his respiration to the conditions of the atmosphere. In case his suffering is greater at first, it often happens that he is compelled to make a temporary change of residence to a point some 1,000 meters nearer the level of the sea. Even during the descent he begins to breathe more easily and feels brighter and stronger.

The inhalation of air which has been artificially condensed, as in a pneumatic cabinet, produces quite similar sensations. An asthmatic patient placed in an atmosphere where the pressure has been augmented by nearly one-half will immediately be enabled to breathe more freely; respiration becomes slower; his excited nerves are quieted, and he feels imbued with renewed vigor.

The mechanical action of condensed air as it affects respiration is the reverse of the action which takes place in rarefied air. A higher atmospheric pressure facilitates the expansion of the lungs, and the condensed atmosphere, by delaying the egress of the air expelled during exhalation, finally effectuates a distended condition of the lungs. The pulse beats become slower at the same time, and the veins, which were surcharged with blood under a diminished pressure, are now emptied more thoroughly. This is the cause of the decrease of congestive conditions in a pneumatic cabinet. The amount of oxygen which we inhale is increased in proportion to the increased condensation of the atmosphere, thereby enriching the blood. If the treatment is continued, this soon makes itself manifest by an increased appetite and a healthier complexion. The invalid gains in strength and vitality. Respiration is facilitated even outside of the cabinet, and by such observations we perceive that the employment of condensed air has after effects, which supposition the spirometer confirms. A deeper and more quiet respiration has been observed in some cases after the elapse of one and even two years.

The air which is admitted into the pneumatic cabinets by means of air pumps can be kept at any degree of condensation. The cabinets, which are of various sizes, are arranged to admit from three to fourteen persons, and naturally great care is taken to have a good ventilation. They generally stand in the center of a lighted hall; their walls are composed of sheet iron and provided with windows which admit ample light for reading. The cabinets are used exclusively for the cure of catarrhal diseases, to facilitate the respiration of asthmatic patients and to improve the condition of the blood of anæmic persons, in which cases the condensed air frequently proves beneficial after all other remedies have failed.

The first pneumatic cabinet was established somewhere in the thirties at Montpellier by a physicist named Tabarie, who later gave the management of it into the hands of a physician. Pravaz soon followed his example at Lyons, and the reports of the two scientists as to their observations made on healthy and diseased persons were presented before the French Academy and to the medical world in quick succession. About thirty years later the idea of putting condensed air to this use spread from France to other countries of Europe, and the largest institution of this kind at present is at Reichenhall, the property of E. Mack, in which fifty-three persons can make use of the heightened pressure at the same time.

In 1841 M. Triger, a civil engineer, introduced in France the idea of using a heightened atmospheric pressure in building subaqueous works, and this gave an opportunity to observe what effect an atmospheric pressure which was much higher than that of a pneumatic cabinet would have upon the workmen. The work under pressure is carried on in an iron shaft, the sides and top of which are airtight. It is sunk to the bottom like a diving bell, while the upper end protrudes above the surface of the water. The fresh air which is continuously pumped in from above expels the water below, leaving the bottom free to be worked upon. The shaft sinks deeper and deeper as the earth is removed, until there may be a pressure of three and one-half or nearly four atmospheres. A pressure of ten meters of water is equal to about one atmospheric pressure.

The effect of the condensed air upon the laborers was found to be surprisingly favorable up to a pressure of two atmospheres. The hard work was accomplished more easily and with less fatigue than in the open air, and in such exertions as running up a ladder they did not get out of breath. Even after working hours the men felt stronger and in better spirits.

But when the pressure exceeds that of two atmospheres the men begin to have certain unpleasant sensations, such as itching and pains and swelling of those muscles which are strained the most. These symptoms do not, however, appear while under the heightened pressure, but make themselves felt during the time that the men are under the normal pressure, and pass away again as they return to their work. The overseers are exempt from these effects. They receive instead a mental stimulus which is manifested by an increased impulse to talk.

If the atmospheric pressure is still further increased, the resistance against exhalation becomes stronger. The action of the respiratory apparatus is weakened by the increased distension of the lungs until it finally becomes almost imperceptible; speech is difficult and whistling impossible. The result of the too rapid contraction of the lungs under a diminished pressure which prevents whistling is the same as that which follows when the egress of the air expelled by the lungs is delayed.

The enlivening influence on the workmen is diminished as soon as the pressure exceeds that of three atmospheres. The slow and imperfect performance of the respiratory function begins to have a detrimental effect upon the gaseous interchange which takes place in the lungs by causing the carbon dioxide to be retained in the blood. The laborers become more easily fatigued, and a decrease of appetite is followed by loss of flesh, if they continue the work. We find, therefore, that there is a limit to the condensation of air, which a man cannot overstep without detriment to himself, but there is a wider limit in this direction than in that of rarefied air.

Experience proves that a temporary change from the normal pressure to an increased or diminished pressure is pleasant and also benefits vitality in various ways. We are able to ascend to any altitude at which the air is rarefied to the desired degree, but the privilege of choosing a denser atmosphere in which to live is denied us. It is only from a few places at very high elevations that convalescents can be sent down to a lower altitude, where they quickly recover by inhaling air which is more condensed and contains a larger proportion of oxygen. The inhabitants of the lowlands are confined to the pneumatic cabinet in their search for these benefits. From what has been said regarding the mechanical change which respiration undergoes, we gather that a temporary employment of condensed air, besides its various other effects, would be a good preparation for the proper performance of the respiratory function in a more rarefied atmosphere.* G. VON LIEBIG.

University of Munich.

THE ZODIACAL LIGHT.

By Lieut.-Col. E. E. MARKWICK, F.R.A.S.

THE season when this phenomenon is visible after sunset is now approaching, and it may be interesting to take stock of what we know about it, which, after all, seems to be surprisingly little. It is generally dismissed in the text books with a pretty short notice, and sometimes is not mentioned at all. Although it can hardly be called a popular object in the sense that Mars or Jupiter is, still there must have been a great number of observations made of it at different times, and one looks for a corresponding definite advance in our knowledge of its interior economy. But the conditions of its visibility in our latitude render exact observation extremely difficult. Like the inferior planets, Mercury and Venus, it is seldom, if ever, seen more than three or four hours after sunset or before sunrise, and cannot be observed on the meridian. Again, its tenuous and ethereal character renders it a difficult matter to note definite particulars of its shape, size or position. In these respects no instrument is of the slightest service; but the observer should be one with a keen eye, which can take in a large area of the sky, and is quick in apprehending differences in brightness of particular areas. No telescope can do this, and, even with a binocular, the field of view commanded is far too small. The best way is to sweep the eye rapidly right and left, up and down—that wonderful faculty of "averted vision" assisting to note very faint degrees of light.

My own experience, based on some sixteen years of observation in different latitudes, is that, provided one has a clear country horizon remote from the glare of towns or electric lights, with a dark clear sky in January or February, there is no difficulty to the ordinary observer in England in detecting, soon after sunset, the pearly cone of the zodiacal light sloping upward from the sun's place. The boundaries are generally ill defined, and the apex has usually to be imagined more or less, so exceedingly delicate is the glow toward the extremity of the cone. Guillemin, in "The Heavens," has a very delicate plate of it, as seen in Japan. In this picture it looks fainter than it is sometimes seen in England.

For all practical purposes the axis coincides with the plane of the ecliptic.

An open horizon has a good deal to do with its visibility. For years I looked carefully for it in England without success, and I think the reason was that trees and other prominent objects, dark against the western sky, must have put my eye out of focus for the faint light. There are some who have not the power or capacity for this class of seeing, and I have before now, when in southern latitudes, pointed it out, quite blazing, to a friend, who, however, could make nothing of it, although it was literally staring him in the face.

Humboldt, in his "Cosmos," has some most interesting remarks on the subject, the more so as they are based on personal observation and considerable literary research.

My first observation of zodiacal light was in Natal, where it was at once palpable. It was in the dry, clear air of the uplands of South Africa, however, that it was seen to the greatest perfection; while in the Transvaal and in Bechuanaland the light was almost blazing—at least, it seemed so to an eye accustomed to astronomical phenomena, not to bonfires. Unless one has been in these circumstances of latitude and climate, it is impossible to imagine what an exquisitely delicate and ethereal object the light is. For there one has great advantages, notably in the transparency of the atmosphere, and the fact that the light is perpendicular, or nearly so, to the horizon. It is extremely difficult, when it slopes at the angle it does in England, to judge of the relative sharpness of the margins; a point which I have studied of late in connection with Dr. Veeder's theory of its duplicity. At Gibraltar, whence I write, it is often most beautifully seen as a whole, and Humboldt refers to its greater intensity in Spain, on the coast of Valencia, etc. From our coign of vantage we have the privilege of looking across the Bay of Gibraltar, with the range of hills beyond Algeciras in the distance, and, except for occasional shipping, this view is free from artificial illumination or glare.

Humboldt thinks that the zodiacal light was unknown to, or at least not mentioned by, the ancients. The word trabes, occurring in Pliny, which some consider means the phenomenon in question, refers to meteors, bolides, and comets. According to Humboldt, it is first explicitly described by Childrey, chaplain to Lord Henry Somerset, in his "Britannia Baconia."

Dom. Cassini was the first to investigate the phenomenon in its relations in space in 1683. Cassini, Humboldt says, maintained that a phenomenon observed by him at Bologna, also by Chardin in Persia, in 1668, was the zodiacal light, but that really this was the tail of the comet of 1668, whose head was at the time below the horizon. This calls to mind the great comet of 1882, which I first saw after perihelion in the beautiful sky of Natal about 4 A. M. The head was below the horizon and the tail sloped upward for many degrees—a most extraordinary vision. Never can that supremely beautiful sight be forgotten, as the comet majestically rose and displayed himself, surrounded by a gauze veil more ethereal than any bride's.

But no one could for a moment mistake the comet of 1882 for the zodiacal light. On the contrary, the view of the great comet of 1880, which I also got in Natal, might have been easily confounded with it, on account of its exceeding faintness and delicacy.

Humboldt considers that a remarkable light seen in 1509 for forty nights consecutively, in the elevated plains of Mexico, was the zodiacal light. He found a notice of this light in an ancient Aztec MS. preserved in the Royal Library of Paris.

Humboldt proceeds to inquire into the nature of the zodiacal light, and considers "a very compressed annulus of nebulous matter revolving freely in space, between the orbits of Venus and Mars, as the material cause" of it. Coming to more modern times, Sir J. Herschel thinks it is "that medium which resists the motion of comets, loaded, perhaps, with millions of tails of these bodies." Still later, the idea is that it consists of myriads of small meteors, each revolving round the sun in its own path, the light reflected from which impresses itself on our eyes as the zodiacal light. This is the opinion of Prof. Pickering, who, in vol. xix of "The Annals of Harvard College Observatory," has discussed many observations with his usual acumen.

It would seem certain from the observed angular distance of the apex from the sun that these meteors extend beyond the earth's orbit; and as the light lies in, or very close to, the ecliptic, we must be perpetually cutting through them as we revolve round the sun. Do we see in our atmosphere the falling meteors which have originally formed a portion of the zodiacal light? We are of the opinion this question can only be settled when that of the relation of comets to meteors is settled, and we know what a dubious matter that is in its purely physical aspect.

Dr. Veeder, of New York, considers that the zodiacal light "does not conform to the plane of the earth's orbit, but to that of the equator of the body which it surrounds, which in this case is the sun itself. As viewed from the earth, these coronal extensions are at times foreshortened, and at times opened out, so as to become more plainly visible. In the spring months, the south pole of the sun is inclined toward the earth, so that the latter is almost exactly in the heliocentric zenith of the southern sunspot belt and coronal extension. Consequently, the particles composing this extension are in a direct line between sun and earth, and, shining as they do by reflected light, like the new moon, they become almost invisible. Coincidently the coronal extension overlying the northern sunspot belt is opened out to its widest extent, and reflects more light earthward than at any other time. Hence, if these extensions become visible as the zodiacal light, the southern edge at this season should be the more sharply defined, and more exactly included within the plane of the ecliptic, because of the lack of illumination described; and the northern edge, on the other hand, should shade off very gradually, departing more widely from the plane of the ecliptic, and this is precisely what has been found to be the case."

My own observations made at Gibraltar most certainly support this view.* It has also been observed by Cassini and others. Dr. Veeder further observes that it is probable that "these coronal extensions serve as conductors of electrical impulses," and are therefore connected with the appearance of aurora.

The question of the variability of the zodiacal light has been much discussed. Humboldt says: "I have occasionally been astonished, in the tropical climates of South America, to observe the variable intensity of the zodiacal light. As I passed the nights, during many months, in the open air, on the shores of rivers and llanos, I enjoyed ample opportunities of carefully examining the phenomenon. When the zodiacal light had been most intense, I have observed that it would be perceptibly weakened for a few minutes, until it again suddenly shone forth in full brilliancy. In some few instances I have thought that I could perceive, not exactly a reddish coloration, nor the lower portion darkened in an arc-like form, nor even a scintillation—as Mairan affirms he has observed—but a kind of flickering and wavering of the light." These rapid apparent changes, however, he thinks, may be partly due to causes acting in the upper strata of our atmosphere.

Olbers convinced himself that "the light is very different in different years, often for several successive years being very bright and diffused, while in other years it is scarcely perceptible." This, of course, is a different sort of variation from the temporary or momentary changes just mentioned. Some modern observers think it decidedly variable in the way mentioned by Olbers—that is, more brilliant on some occasions than on others. But we must bear in mind two things in considering this question. First: as seen in England the total apparent length of the cone decreases gradually as the season of visibility goes on. Thus, for the evening apparition the length as observed in March and April is nearly always markedly less than when seen in January and February.† Hence, because the length of the cone appears different as seen at dates separated by an interval of (say) a fortnight, it is not necessarily to be inferred that the brilliancy has changed in that interval of time. Second: we all know how after a spell of dull or wet weather an unexpectedly clear night suddenly turns up. On the last occasion of a clear but "poor" night, the zodiacal light perhaps looked poor too. Now, on the very clear evening, it is seen under fine conditions, and naturally the finer and more delicate parts stand out clearly. But this is not variability. We cannot focus our sight on to this delicate object as on a variable star, and the circumstances are such as do not admit of the application of exact photometry to the case. To decide this question we need a regular series of systematic observations made in some clear and serene sky, like that of Peru or the Transvaal, night after night and year after year. Such observations should give, according to a fixed method, the length and breadth; also the brightness, say at certain fixed altitudes, as compared with the Milky Way. It is only from such a record that the question of variability can be settled. Very possibly, changes

in the density of different parts of the zodiacal meteors or cosmic dust may take place from time to time, and, consequently, changes in brightness. But I do not think that so far they have been fairly proved.

Some observers have noted a ruddy tint, but I confess that I have never detected this.

Good observers, like Admiral Smyth, acknowledge many disappointments of not catching it; and to anyone who has not yet seen the light, but wishes to do so, I would offer the following suggestions: Time, middle of January to middle of March; locality, remote from any large town or collections of lights. From some of the breezy commons and downs of Surrey or Sussex, well to the south of the metropolis and free from trees, one can command a grand sweep of sky. Better still if the observer has a sea horizon to the west, for then, provided there is no shipping, he may be absolutely certain that no artificial glare exists. Choose a brilliant evening, such as sometimes comes after heavy rain. There must be no trace whatever of moonlight, which blots out our faint subject. Keep on the lookout, say, from a quarter of an hour after sunset. Do not strain the sight by looking fixedly at a star or in one place. Cast the eye occasionally over the western sky toward the horizon, and with the above circumstances favorable, you should have no difficulty in "catching" the phenomenon and "holding" it, too. I am not quite prepared to say whether nearsighted persons would be handicapped in this search. Possibly spectacles may in some way impede vision in sweeping over a large area of the sky. There must be a slight loss of light, even through one lens only. Personally, I am blessed at present with a long sight, which does not need any assistance in the way of glasses. When once seen, it is comparatively easy to see it again another night, as we then know what sort of a thing it is we are looking for.

It is curious that the zodiacal light has not been seen during a total eclipse of the sun, and it would therefore seem that its light is decidedly inferior to that of the corona. At the same time, in such a consideration one must not omit to take account of the vast area of illuminated earth and sky which surrounds the moon's shadow cone. The darkness of an eclipse is not that of night.

Would an observer from Neptune, supposing he could do without any atmosphere himself, see the sun as a "nebulous star," with the zodiacal light extending on either side like a delicate comet? Very probably—with many a comet plowing through it, which our own atmospheric veil prevents us by its brilliant glare from seeing. Take as an instance the comet seen close against the sun during the total solar eclipse visible in Egypt in 1882.

There are two other phenomena connected with the zodiacal light, viz., the gegenschein, or counter glow, and the zodiacal band. The first is a faint patch of light seen very nearly opposite the sun's place; the other is a prolongation of the zodiacal light to the gegenschein. Both these are excessively delicate phenomena and require the finest sight and sky. Although I consider I have a good eye, I have never seen either. Even Prof. Pickering can only say that "the evidence for the actual existence of some light opposite the sun becomes tolerably strong." Still, there can be but little doubt of the existence of the gegenschein from the observations of Brorsen, Schmidt, Heis, Backhouse, Lewis, Barnard and others. But the ordinary observer can hardly hope to detect this or the zodiacal band. —Knowledge.

FISHING DURING THE TRIP OF A MERCHANTMAN.

A SLIGHT breeze is blowing. With all its sails set, a three-masted merchantman is plowing its way through the blue waters of the Atlantic. Astern, upon the poop, some of the crew are at work making foot ropes fast to a new mainsail. The captain is striding the deck, casting a glance at the sails, at the steersman and at the sea, and punctuating his promenade with orders: "Keep your eye on the helm!" says he to the steersman. "Tauten the sails there!" exclaims he to the sailors. But see yonder, in the distance, those black objects that are leaping upon the sea and marking their passage with a streak of foam! "Aha! they are porpoises! Boatswain, get out your harpoon, quick! And the rest of you there, come to the forecastle!" At the captain's exclamation every one raises his head, the cook comes out of his galley, the cabin boy leaves his table utensils in confusion, and all run to the forecastle. The harpoon is provided with its line and handed to Loic, the most expert of the crew in this sort of fishing. Loic climbs down beneath the bowsprit, and here, his feet firmly planted upon the backstays, his left hand grasping the martingale, and his right brandishing the harpoon, he waits.

PORPOISE FISHING.

In the distance, the porpoises tack about and point their noses toward the ship, and then, turning in the opposite direction, put the patience of the fishermen to a severe test. Loic whistles in order to attract them. Finally, three of them separate themselves from the group and come direct for the ship, to which they are attracted by its copper shining in the sun.

"Attention, Loic! there they are!" and the three cetaceans pass by as quick as a flash in leaping at a couple of yards from the vessel's stem. Loic's uplifted arm shoots forward like a released spring, and one of the porpoises, pierced through and through by the harpoon, struggles at the end of the line and makes desperate efforts to escape in tinging the blue water of the sea with its blood. "There he is!" cries Loic in regaining the forecastle.

The animal is allowed to struggle and exhaust itself for a moment, and is then gently hauled up alongside, where a line with a slip noose is made fast to its tail, so that it may be lifted on board by means of a capstan. From the forecastle it is sent to the deck, where the harpoon is removed, and it becomes the temporary property of the cook. Under his expert hand, the porpoise is converted into savory steaks and into huge meat pies that will somewhat vary the mess of pork and beans and hardtack and salt mackerel that forms the basis of the food of the crew of merchantmen.

Shark Fishing.—A shark has been following the ship for a couple of days, awaiting some windfall or other, perhaps the fall of a man from a mast. Its proximity is annoying, and, although the catch is not worth much, an endeavor is to be made to capture it. At the captain's order, the boatswain goes to get a huge hook provided with a chain six feet in length used for this sort of fishing. A rope is attached to this, and the hook having been baited with pork, the whole is trailed astern. Master Shark is always on hand, disporting in the blue water, swimming around the ship, passing under the keel, sometimes disappearing for an hour or more, and then betraying his presence by his fin. On board, he is being watched, in order to see if he will notice the bait. Finally, the odor of the pork attracts him. He pounces upon it, rubs his nose against it in order to ascertain the nature of the thing, turns about suspiciously, makes a point seaward, then suddenly returns, and, his resolution having been taken, turns upon his side, opens his jaws and swallows the bait. Then the hook operates, and the shark begins his dance. His formidable bounds make the stern of the ship tremble amid splashes of foam. The line is paid out a little, and then, when the motions of the shark become slower, the ship proceeds smoothly. Now that he is taken, and well taken, there is nothing to be done but tow him along for a few hours, and with the eight knots that the vessel is making he will soon be mastered.

The next morning, before washing, the captain comes to take a glance. "He can be hauled in now; the old fellow is half dead. Pull in the line to see!" says he. The line is pulled in, and the shark no longer gives any sign of life. It is the moment to take him on board. The brigantine is brailed up and the sheets of the main boom are secured. A winding tackle coming from the mizzen mast is attached to a strong ring of cordage surrounding the main boom, and to the latter is hooked a pulley block through which the line is passed. Then all hands begin to haul, and the shark comes under the taffrail. "Hoist away, my hearties!" The head now comes out of the water, and gradually the body makes its appearance. Sometimes the shark seems to take a new lease of life, and lashes the water with furious blows of his tail. In such a case, he is submerged again. Master Shark this time does not budge. A strong slip noose is passed under the caudal fins, the main boom is braced leeward, and the end of the line is hauled by hand, and guided by pulleys to the capstan upon the forecastle. Then all hands heave at the capstan until the shark is hauled up and laid upon the poop. From there it is dragged to the deck.

There is often a terrible awakening. Then, beware of the blows of the tail and especially of the snapping of the teeth. The animal struggles in opening and closing its formidable jaws with a sharp click, while its tail pounds the deck planks. The men, armed with axes, then attack it and aim especially at the head and tail. Finally, cut and slashed, the shark no longer budges. A few slices of its coriaceous and oily flesh are set aside for the crew, while the captain reserves for himself the vertebral column, which, once arranged and a ramrod inserted in the interior, will serve as a cane, and, at all events, as a trophy. As for the remains, these, thrown overboard, will regale the bonitas and other fishes.

Capture of Albatrosses.—The capture of the albatross, like that of the shark, is, upon the whole, merely a pastime, its oily flesh, smelling like fish, not proving a very agreeable and delicate food. The albatross furnishes the pipes and tobacco pouches of merchantmen sailors. It is also a sort of certificate of the passage of the Cape.

The process of capturing the bird is as follows: To the end of a strong line is fastened a hook of the size of those used in trailing for tunny. This hook is carefully concealed in a piece of thin canvas cut into the form of a fish, or is baited with some sort of detritus or other, and the whole is thrown into the sea. The albatross, which is voracious by nature, never fails, whenever it

sees the bait, to pounce upon it. As soon as it finds the hook fastened in its bill, it spreads its wings and flies away in endeavoring to free itself by violent struggles. If other albatrosses or frigate birds chance to be in its vicinity, they take flight with strident cries in describing circles around the prisoner and in seeming to seek a method of delivering him. A slight pull is given upon the line, and, when the bird is of large size, two men are none too many for the work of landing it upon the deck of the vessel. Once on board, it only remains to kill it. Some put it to death by thrusting a strong sail needle into its skull—a cruel process that has the drawback of not being followed by an immediate result. Others strike it upon the neck with a club. The albatross is not a very handsome bird, and it is remarkable only by the huge size of its wings, the spread of which sometimes reaches twelve and even fourteen feet in adult individuals.—L'Illustration.

SHARK FISHING.

CAPTURE OF AN ALBATROSS.

DREAMS.*

At the psychological congress last year, Dr. J. Mourly Vold, of Christiania, reported some experiments which he had undertaken with regard to the artificial stimulation of visual elements in dreams. The subjects included a large number of persons of different ages, sexes and classes, but were mostly adults of an intellectual type above the average; all those selected were good dreamers. Dr. Vold arranged the experiments as follows: To each of his subjects he sent, from time to time, a package containing figures of animals, well-known objects, etc., cut out of white paper, or some striking colored object—a flower, coin, etc. The package was only opened after the subject was in bed. The contents were then displayed on a black background, and scrutinized closely for a considerable time—usually from two to ten minutes—without intermission; in some cases for half an hour or more, interspersed with periods of rest. The light was then put out, and the eyes closed. In the morning, immediately on awaking, the subject wrote a report of his dreams, together with the conditions of fatigue the night before, length of sleep, etc. Prof. Vold supplemented these reports, when it seemed desirable, by verbal questionings. Some three hundred separate tests of this nature were made.

On examining the results, it was found that the character of the dreams depended on a number of distinct factors, such as the quietness and uneventfulness of the preceding evening, but that it did not depend (so far as could be discovered) on the specific time of experimentation or of awakening, nor on the obtaining of after-images from the given objects. The size, form and color of the objects were rarely all reproduced together, but one or two of these conditions often reappeared in the dreams. The form and size of the object were frequently reproduced, either as in the original or with some modification; this transformation often occurred in the dream itself. The color exerted an influence independent of the other factors, and this proved the point of greatest interest in the results. When the given objects were black or white (with complementary background) the dreams in many instances exhibited recurring contrasts of light and shade. Often the object reappeared (with considerable change of form) in the same color as shown; or some other object appeared in the given color, which might be a very unusual one for it to take; in this case, either the color of the background reappeared also, or no background was discerned. In experiments with colors other than black and white, the given color also tended to reappear; this was especially the case with red; the color might recur in the same tone, saturation and brightness as in the given object, or it might appear modified in these respects; or, such a modification might take place in the course of the dream, as in the case of modifications of form.

The author concludes from these experiments that the visual apparatus immediately before awakening reproduces to a certain extent the condition present at the time of falling asleep; but that the original associations of form, size, color and abstract representation are broken up, and new syntheses constructed in their stead. In these new syntheses the common visual forms, or abstract representations of daily life, are apt to become associated with the colors or outlines of objects which affect the organ of vision just before the beginning of sleep. Some such theory seems necessary to account for the facts brought out in these experiments.

In a note in the Revue Philosophique, M. E. Goblot speaks of the connection between dreams and the act of awakening. He urges the view that dreams which we remember are those which accompany the latter state. The passage from sleep to wakefulness, like that from wakefulness to sleep, is not an instantaneous process; it occupies at least an appreciable time. The dreams which we are able to remember afterward are those that belong to this period of transition; and this fact, the author insists, is more than a mere coincidence. When we analyze a remembered dream, we find in its last stages always some elements of external sensation, which gradually (or quickly) unfold into the conditions of normal waking life. All the organs of sense and movement do not wake at the same time; and to this is due the transition period just mentioned. It is only the dreams of this period—in which some of the conscious elements are those of sleep, while others belong to waking life—that we are able to connect through memory with after-consciousness; and the memory connection is due to precisely this association of elements of waking consciousness with the dream elements. This is the reason, says M. Goblot, why we do not remember those dreams occurring early in the night, in which we talk, cry out, gesticulate, or walk, though such dreams can scarcely fail to have been most vivid; for, unless they result in our awakening, there is no associative element in waking consciousness capable of recalling them. Even those dreams which we do recall have usually so slender an associative element that they are speedily forgotten, unless we take special pains to impress them upon the memory by writing them down or rehearsing them soon after waking.

The present writer would suggest that more attention be paid, in the study of dreams, to determining the normal visualizing power of the individual. It is well known that some persons habitually "visualize" their visual memories (i. e., represent them in the form and color of the original); while others, including those more accustomed to abstract thinking, are lacking in this power, and substitute words or other symbolism for the visual picture. The same is true to some extent of sounds and other classes of sense memories. In sleep, where outer stimulation is practically wanting, central images play the chief rôle, and in the absence from consciousness of more vivid presentations are mistaken by the subject for primary sense impressions. It would seem, then, that there ought to be a broad distinction of some sort between the dreams of the visualizing and symbolizing types of individuals. Whether good visualizers are better dreamers, or whether their dreams are merely of a different character from those of symbolizers, remains to be seen. But certainly the question is well worth investigating. So far as I know, no attempt has yet been made to gather data bearing on this point.

* The American Naturalist.

SOLUTION FOR PREPARING COLOR SENSITIVE PLATES.

H. Vollenbruch, in Deutsche Photographen Zeitung, maintains that plates sensitized with erythrosin silver citrate are not only more sensitive to color impressions, but also have better keeping qualities than ordinary erythrosin bathed plates.

For depression of the over-active blue rays he recommends the addition of picric acid to the coloring solution. The picric acid erythrosin silver citrate ammonia solution is prepared as follows:

Solution I.

Citrate of potassa	1 grm.
Distilled water	10 c. c.

Solution II.

Silver nitrate	1 gr.
Distilled water	10 c. c.

Both solutions are mixed and a white precipitate is formed which is allowed to subside. The clear supernatant liquid is poured off carefully, precipitate washed with water, allowed again to subside, and the wash water again decanted. This process is repeated two or three times. Finally a large bulk of water (30 cc.m.) is

added to the precipitate and well shaken; 5 c. c. of this is reserved, the remainder is treated to ammonia, drop by drop, until the precipitate is redissolved. Now add the 5 c. c. of reserved solution and shake the whole until every particle is dissolved. Then make up the solution to 50 c. c. and filter; this forms Solution III.

Solution IV.

Distilled water	300 c.c.
Pure erythrosin	1 gr.

Under lamp light the 50 cc.m. of Solution III. are poured slowly with repeated shaking in Solution IV, by which the originally beautiful red is converted into a dirty turbid bluish red somewhat viscid fluid; add—

Solution V.

Picric acid	4 grms.
Absolute alcohol	30 cc.m.

Shake well and add to the whole 33 cc.m. ammonia (specific gravity 0·91), wherewith the beautiful red color is restored.

After the filtration call this Solution VI. This solution keeps well. The slight deposit formed is redissolved on shaking.

The plates are sensitized as follows: The plate to be sensitized is first laid in a tray of distilled water for two or three minutes, then bathed in a mixture of 1 c.c. ammonia for one minute and finally for two minutes in a bath composed of the following:

Color Solution VI	10 cc.m.
Distilled water	300 cc.m.

The plate is well drained and dried in a perfectly dark room. These plates keep well for several months.—American Journal of Photography.

THE PRINTING-OUT PLATINOTYPE PROCESS.

THE statement made by Mr. Cembrano in his presidential speech before the convention at Yarmouth, England, to the effect that "a paper is much needed possessing the ease and simplicity of manipulation, permanency of results and beauty in quality of platinotype, combined with the certainty in printing of what are commonly called printing-out papers," naturally suggests to one the printing-out platinotype process, which seems to have been much neglected in England.

This process was suggested by Pizzighelli in 1887, and differs from the other platinotype processes in that the developer is in the sensitizing solution. As a rule, sodium ferric oxalate is used, which, by exposure to light, is reduced to sodium ferrous oxalate and sodium oxalate, according to the equation:

$$Na_6 Fe_2 (C_2 O_4)_6 = Na_4 Fe_2 (C_2 O_4)_4 + 2 Na_2 C_2 O_4 + 2 CO_2.$$

Sodium ferric oxalate occurs in fairly large green crystals, which are perfectly stable in the dark, and are easily soluble in water (about one in two), and when spread on paper it gives a yellowish green film.

As damp is necessary for the full development of the image, it is necessary to expose it to aqueous vapor before printing; otherwise the printing is precisely the same as for any other of the platinotype papers. The best way of dampening the paper is to fill a developing dish with warm water, and just hold the paper for about three minutes in summer and one and a half minutes in winter, film face downward over the same. It is frequently recommended to breathe on the paper while it is in the printing frame; but this is hardly to be commended, for the simple reason that part of the paper near the middle of the frame, as a rule, gets less moisture, and therefore shows fainter in the finished print; further than that, the negative, unless covered with a piece of plain paper, also becomes moist and absorbs some of the platinum or iron salts, and thus stains are caused which are extremely difficult to eradicate.

For this process there is no doubt that Rives or Saxe papers are the best, though Whatman's or Creswick papers may be used.

The sensitizing salts should be made up into the form of stock solutions. The sodium ferric oxalate solution should be made by dissolving, by the aid of a gentle heat, 240 grains in 1 ounce of distilled water, and the solution filtered and labeled "The Iron Solution."

The chloro-platinite of potash may be dissolved in the proportion of 1:6, or a 15 grain tube in 90 minims of distilled water.

Besides these will be required a ten per cent. solution of sodio-chloride of platinum, which is added to the sensitizing solution to give brilliancy or greater contrast, and is especially useful for thin, flat negatives.

A solution of gum arabic must also be used, and 1 ounce of the best white gum arabic in lumps should be dissolved by constant stirring in 2 ounces of distilled water, and then filtered through nainsook, using pressure if necessary.

The sensitizing solution itself is prepared by mixing, preferably in a flat dish or saucer:

Chloro-platinite solution	116	minims
Iron solution	120	"
Gum arabic	116	"

The above quantity is sufficient for 480 square inches of paper. The solution should be brushed over the paper with a broad, flat brush, not too soft, and then the marks evened out with another till it has lost all glaze, then quickly dried, and the process of drying should not take more than half an hour. Great care should be exercised in the choice of the brushes. A soft camel's hair brush will mop up too much solution, while a hard brush is apt to cause marks in the sensitizing.

Sepia-toned pictures may be obtained by the addition of palladium or mercury salts to the sensitizers, but the results obtained by these are by no means satisfactory, nor is there any good method of obtaining sepia tones direct by this process.

Mercury gives, as a rule, yellowish whites, and the tones are not even, that is to say, the high lights may be sepia, the half-tones gray, and the shadows black. With palladium the difficulty is to keep the paper, and it must be printed out dry and then developed, or else variations in tone and general reduction may ensue.

A formula strongly recommended by Watzek for the mercurial paper is:

Sodium ferric oxalate solution	168	minims
Potassium chloro-platinite solution	100	"
Potassium chlorate solution	4	drops
Mercuric chloride solution	84	minims

All these solutions should be saturated. It will be found necessary, if this be used, to give the raw paper at least two coatings of plain two per cent. arrowroot size; but it is preferable to use the gum arabic solution in about the same proportion as suggested for the black paper, and also to replace the chlorate of potassa by a like quantity of sodio-chloride of platinum, which keeps the white purer.

For the palladium paper the following may be used:

Iron solution	120	minims
Chloro-platinite solution	80	"
Potassio-chloride of palladium solution (1:8)	20	"
Gum arabic solution	116	"

It must not be forgotten that this paper must be absolutely dry during printing, and only developed by steam afterward.

The subsequent treatment of these prints is precisely the same as for ordinary platinotype, namely, the use of the three acid clearing baths, and then well washing. The process is not a difficult one. The chief difficulty is the drying.—British Journal of Photography.

DELICACY OF VARIOUS REACTIONS FOR METALS.*

By Dr. B. NEUMANN.

THE following table, in its rearranged and improved form, is the result of the author's personal experience and comparison with well known authorities:

Metal.	Reagent.	Sensitiveness.
Arsenic (as arsenious acid)	Hydrogen Sulphide	1:3,600,000
	Sodium Sulphite and Stannous Chloride	1:20,000
	Sodium Thiosulphate and Hydrochloric Acid	1:1400
	Lime Water	1:4000
	Cupric Sulphate	1:8640
	Argentic Nitrate	1:200,000
	Electrolysis	1:1500
	Electrolysis (with Fe and Cu)	1:133,000
	Marsh's Test (Mohr)	1:500,000
	Marsh's Test (Devergie, Otto)	1:100,000
	Bettendorf's Test	1:1,000,000
	Fleitmann's	1:5000
	Gutzeit's	1:1,000,000
	Reinsch's	1:250,000
	Fresenius-Babo	1:5000
	Zwenger's	1:50,000
Antimony	Zinc (Fresenius)	1:30,000
	Zinc (Rideal)	1:20,000
	Hydrogen Sulphide (Rideal)	1:41,000
	Hydrogen Sulphide (Neumann)	1:100,000
	Lime Water	1:1200
	Potassium Carbonate	1:2000
	Electrolysis	1:1,500,000
	Electrolysis (by Fe and Pt)	1:80,000
Bismuth	Potassium Iodide (Stone)	1:4,000,000
	Potassium Iodide (Field)	1:1,000,000
	Hydrogen Dioxide	1:100,000
	Tartaric Acid and Stannous Chloride in K O H Solution	1:210,000
	Potassium Cinchonylhydroiodide	1:1,000,000
Cadmium	Sodium Sulphide	1:250,000
	Potassium Ferrocyanide	1:10,000
	Sodium Hydrate	1:50,000
	Sodium Carbonate	1:20,000
Cobalt	Potassium Ferrocyanide	1:60,000
	Potassium Cyanide and Ammonic Sulphide	1:50,000
	Sodium Sulphocyanate	1:3000
	Potassium Xanthogenate	1:100,000
	Ammonia	1:1,000,000
	Sodium Hydrate	1:10,000
Copper	Potassium Ferrocyanide (Wagner)	1:200,000
	Potassium Ferrocyanide (Cooper)	1:4,000,000 1:11,750,000
	Potassium Ferrocyanide (Neumann)	1:250,000
	Ammonia (Wagner)	1:25,000
	Ammonia (Neumann)	1:50,000
	Ammonia (Will)	1:100,000
	Ammonia (Cooper)	1:1,000,000
	Potassium Xanthogenate (Wagner)	1:200,000
	Potassium Xanthogenate (Schwarz)	1:1,000,000
	Hydrogen Sulphide (Cooper)	1:15,000,000 1:4,150,000
	Hydrogen Sulphide (Neumann)	1:300,000
	Potassium Arsenite	1:10,000
	Sodium Sulphide	1:700,000
	Sodium Hydrate	1:30,000
	Potassium Carbonate	1:14,000
	Hydrobromic Acid (Neumann)	1:10,000
	Hydrobromic Acid (Sabatier)	1:10,000,000
	Hydrobromic Acid (Endemann and Prochazka)	1:100,000
	Sodium Sulphite and Pyrogallol	1:3,000,000
	Electrolysis (with Iron)	1:15,000
	Electrolysis (with Pt and Zn)	1:4000
	Electrolysis (with Pt and Br)	1:1,000,000
	Guaiac Tincture and Alkali Chloride	1:10,000
	Guaiac Tincture+HCN	1:500,000
	Guaiac Tincture Alcohol+HCN	1:10,000,000
Ferric Oxide	Potassium Ferrocyanide	1:500,000
	Potassium Sulphocyanate	1:1,600,000
	Ammonia	1:800,000
	Ammonia and Thioglycolic Acid	1:200,000
Ferric Oxide	Extract Logwood	1:15,000,000
	Tannic Acid	1:200,000
	Salicylic Acid (Smith)	1:32,000
	Salicylic Acid (Almén)	1:100,000
	Ammonium Sulphide	1:2000
	Sodium Sulphide	1:700,000
Ferrous Oxide	Potassium Ferrocyanide	1:440,000
	Ammonia	1:500,000
	Oxalic Acid	1:5000
	Sulphuric and Nitric Acids	1:300,000
	Tannic Acid	1:440,000
	Sodium Sulphide	1:700,000

* Pharm. Zeitung, xlii, page 148, (Drug Topics.)

Since it is difficult to get flues quite airtight and smooth enough not to interfere with the cleaning, and in order to prevent partial stoppages which may be caused by materials falling down during building, it has been proposed to build the flues directly of stones provided with hollows of the desired sections. In the stones of Zombrolch, of Hagen in Westphalia, made of cement, beton, etc., these hollow channels are arranged eccentrically. Three of the walls have the same thickness, the fourth is thicker. On the upper thick surface a step is formed. If, then, the stones are fitted into one another so that the thicker sides lie alternately right and left, the inner channel will be straight and the stones will rest firmly on one another.

ENGINEERING NOTES.

The first German town to adopt the motor car for cab service is Stuttgart. Rubber tired cabs run there beside the usual horse cab; they are driven by a four horse power motor, which makes them quicker than the ordinary cab, especially for long distances and country driving, and the charge is the same as for ordinary cabs.—Uhland's Wochenschrift.

It is stated the Chilean government has decided to appropriate $500,000 for encouraging the development of iron and steel foundries in that country. One hundred and twenty thousand dollars will be given to an American syndicate as a bonus for establishing an iron foundry, and the residue of the sum mentioned is to be similarly distributed. Government reports say that iron ore exists in abundance in Chile.

H. C. Fairbanks, of Sibley College, while constructing a gas engine, observed a singular though probably not exceptional phenomenon which, so far as known, has not been previously described. The machine exhibited a great loss of heater efficiency, which was unaccounted for and was not affected by any changes made in the process of repair. Finally it was suspected that the conductivity of the metal of the cast iron "fire pot" had been impaired by oxidation or otherwise, and it was replaced by a new one. The engine at once started off at full power and regained its original efficiency.

The Engineering News says: "Brazilian railways, says a Paris news item, are to be farmed out to an English-French-German syndicate. A provisional contract has been made between the Brazilian government and the Rothschild Frères, the Discount Bank of Berlin and the Comptoir d'Escompte of Paris. A company is to be formed to take over the administration of the Brazilian railways. The capital will be $10,000,000, half of which will be taken by the English group and one-quarter each by the French and Germans. One of the conditions is that this capital is to remain in Europe for two years, and numerous sinecure offices on the railways will be suppressed and abuses in administration reformed."

The authorities of the Madras Presidency have decided to invite proposals for the utilization of the water power that is at present running to waste in the flow from the Periyon Lake, says The Trade Journals Review. There are immense industrial possibilities in the scheme. The fall is approximately 900 feet, and for nine months of the year the flow varies from 500 to 1,100 cubic feet per second, the lowest average being equal to a force of 30,000 horse power. The Indian government is prepared to rent any part of the whole supply at a certain rate per cubic foot per second, so that small factories could be established; and as a large quantity of jute and other natural products abound at Madras, there is a splendid opening for extensive mills for its preparation into finished goods. The government intends to give the first year of the concession free, charging only a fifth for the second year and continuing to add a fifth for each successive year of the lease. There is also the possibility of power transmission to considerable distances. As this has already been done in other parts of the world, there is no reason why it should not be financially successful in India.

That galvanized sheets which are made of steel, with the oxide formed in rolling removed, and then coated with spelter, are not more generally used in boiler or tank works is because the advantages thereof are not sufficiently understood, says the American Boilermaker. The extreme cheapness of steel plate and improvement in manipulating same have led to the substitution of steel plate stacks and chimneys for brick. It is, however, well for boilermakers to remember that the action of moisture, especially when impregnated with sulphur arising from soft coal, has a destructive influence on steel plates, rusting rapidly, particularly in the lighter gages. This may be delayed by frequent painting or varnishing. The coating of spelter on steel sheets is impervious to moisture, and therefore the life of the metal is preserved indefinitely, especially where it may be painted with the ordinary commercial stack or boiler paints. We would remind boilermakers that unless they call the attention of their customers to this fact, they will find a large and profitable part of their business leaving them, on account of the short life of the ordinary steel stack as now made, because the first cost of the brick chimneys will be of less importance than the inconvenience and cost of having to replace a steel stack or chimney.

The following table gives the railway mileage of the five great continents of the world, says The Engineer. The first column represents the totals in 1895, the second in 1891, and the third shows the increase in the four years:

	1895. Miles.	1891. Miles.	Increase.
Europe	155,284	141,552	13,732
Asia	26,890	22,023	4,867
Africa	8,169	6,522	1,647
America	229,722	212,724	16,998
Australia	13,888	12,322	1,566
The world	433,953	395,143	38,810

The percentage of increase in mileage was greater in Africa than in any other continent; but this great percentage was only 1,647 miles. The South African Republic led in new construction, building 401 of its 616 miles between 1891 and 1895. Cape Colony followed, and it has more railroads than any other African country, followed by the French possessions Algiers and Tunis. Egypt made an addition of 31 per cent. to its mileage in the four years in question, as did also the Orange Free State. Just about half of the African mileage is in the comparatively small area of South Africa. Among European countries the rank in mileage is as follows: Germany, France, Russia, Great Britain and Austria. No other country has so much as 10,000 miles. The largest increase in mileage since 1891 has been in Russia—4,146 miles and 21·4 per cent. No other country in Europe added half so much to its mileage. But Spain gained 18·3 per cent. and Sweden 17·7 per cent. The gains in France, Germany, and Austria-Hungary were from 6½ to 7 per cent.

MISCELLANEOUS NOTES.

Salt has just been put in the allowance of food which the British government gives its sailors, though other condiments were allowed in the rations. When "salt horse" was the main staple of diet there was no need of it, but although this was changed on men-of-war long ago, the Admiralty has only recently discovered that the men have no salt. They have been obliged to buy it out of their wages for years.

Since 1797 there have been 1,100 theater fires with 10,000 fatalities, according to Mr. Sachs' "Fires and Public Entertainments," just published. Of these, 462 took place in the United States, 139 in Great Britain, and 101 in Germany, France having nearly the same number. London has had 35 fires and Paris 28. Out of 343 theaters destroyed by fire, one-half were burned within ten years after they were constructed, forty of them within the first year.

Regarding the formation of petroleum, Prof. Dr. C. Engler, an authority in this field, has become convinced, in a recent voyage to the Orient, of the correctness of his theory advanced about thirty years ago, viz., that petroleum has formed from the remains of an extinct fauna. On the other hand, the results of investigations by Cloez supported Mendelejeff's hypothesis of the formation of the petroleum by the action of water and salt solutions on carbide of iron, for Cloez obtained, by the action of water on crude iron and on magnesian iron a number of hydrocarbons of the same combination as that of earth oil.

Endless are the inventions which the bicycle has been the means of stimulating. We notice that a Glasgow inventor has patented an improved method of impregnating materials, such as chrome tanned leather or cotton, canvas or like fabrics, with a solution of India rubber, more especially the materials for use in the construction of pneumatic tires. The material, when dry and warm, is immersed in a bath of naphtha, benzine or other solvent until thoroughly saturated. This, when drained of unnecessary excess, is placed in a warm bath of India rubber, gutta percha or other solution with which the material is to be impregnated, the solution being at from 100° to 110° F. The material is then dried and treated to remove unnecessary surface deposit. The patentee does not say in what respect his materials treated in this manner will be superior to existing manufactures of this kind.

An excellent movement in behalf of ascertaining the value of different varieties of native stone found in California for structural purposes has been undertaken by Prof. Lawson, of the department of geology in the University of California, at Berkeley. From quarries or outcrops where quarries are possible, and where the stone is fairly uniform, it is proposed to secure two blocks of stone, one a twelve inch cube dressed differently on different faces to show the qualities of the stone, and a four inch cube, similarly dressed, for preservation in the college. In cases where the rock has ornamental qualities and varies in texture and color, as in the case of marble deposits, several such blocks would be required fairly to represent the prevailing characteristics; and then there may be cases where, owing to special structures, the stone will appear to better advantage in the form of slabs or columns. These specimens, properly cut by skilled operators, are to be made part of the university's permanent economic exhibit, and such a collection will, it is believed, be made of positive practical value in determining the kind of stone best adapted for constructive purposes.

Materials containing natural dyestuffs and tannin are reduced by a firm in Milan by means of sulphites or bisulphites to compounds which are more slightly soluble (with the exception of the products obtained from quebracho, hemlock and pine extracts) than the starting materials, but show a considerably better behavior in dyeing. Concerned are: Yellow wood, fustic, quercitron, hemlock, quebracho and pine. The conversion takes place at a higher temperature and higher pressure. Thus yellow wood extract, when heated from 110° to 115° C. with bisulphite of sodium of 35° B., affords a substance which produces pure yellow shades of great beauty and intensity upon alumina and a chrome mordant. One part of the new compound dyes upon alumina about equally as strong as one and a half parts of pure yellow wood extract. A similar proportion is shown by fustet and quercitron extracts. From quebracho, hemlock and pine extracts, however, upon heating with bisulphite of sodium from 100° to 150° C. products are obtained which are readily and entirely soluble even in cold water. Considering the high demands in the quick tanning processes for pure and clearly soluble tanning extracts, the new products are regarded with great interest.

A unique idea receives practical realization at the great dyeing plant of Messrs. Brownlow & Standfield, Leeds, England, in a new and peculiar method by which cloth gets a different shade on each side, the necessity of an extra lining being thus done away with. In this process the cloth or material to be treated is first dyed through in any shade of color in the usual manner, then finished by the ordinary processes, after which it is taken to a printing machine provided with a roller engraved all over uniformly with diagonal lines cut deeply and running in one direction over its surface, with diagonal lines cut less deeply and running in the other direction. This roller dips into a bath of thickened color of the required shade and carries it up to the cloth, which is by means of other rollers brought into contact with the dyeing roller; the latter, in order to prevent the color penetrating too deeply, is carefully adjusted in its pressure, and thus the second color is kept from going more than half way through the piece. Screw levers are also arranged upon each end of the roller for adjusting the pressure. After the second color has been applied the cloth is steamed and finished in the ordinary way.

The tensile strength of copper is 33,079 pounds at 122 degrees Fah.; 32,187 pounds at 212 degrees; 30,872 pounds at 302 degrees; 26,981 pounds at 482 degrees; 25,420 pounds at 545 degrees; 22,302 pounds at 602 degrees; and 11,054 pounds at 1,010 degrees Fah. When alloyed with tin to the proportion of 8 of the former to 1 of the latter, the tensile strength is 50,000 pounds per square inch of section.

SELECTED FORMULÆ.

Metal for Locomotive Cylinders.—At a recent convention of the American Railway Master Mechanics' Association one of the members gave a mixture used in making metal for locomotive cylinders, valves, and valve seats. This mixture consists of 20 per cent. steel castings, old steel springs, etc., 20 per cent. No. 2 coke iron, and 60 per cent. scrap. From this it was stated a good solid metal could be obtained, the castings being free from honeycombing, and finishing better than the ordinary cast iron mixture, over which it had the advantage of 24 per cent. greater strength. Its constituents are: Silicon, 1·31; manganese, 0·33; phosphorus, 0·65; sulphur, 0·068; combined carbon, 0·62; graphite, 2·45.

Foundry Facings.—The description of facing sand, which Mr. H. F. Frohman gives in the paper which he read before the Western Foundrymen's Association, is just about as clear an explanation as could be desired by any one seeking to know the rationale of certain operations in the ironfounder's craft. It is free of all chemical terminology, which too frequently serves to confuse and obscure simple phenomena. It explains in the simplest language exactly that which working founders want to know. He tells how the most common facing to mix with the sand is coal dust, and gives the reason for it. The crushed coal is mixed with the sand which is nearest to the surface of the mould, in order to break up the particles of sand, so that when the molten metal comes into the mould it does not fuse the sand to a hard mass similar to glass, but allows the coal to burn away, thus leaving the sand in a separated condition, so that when the casting has cooled these separated particles of sand will readily drop off. This can be verified by putting a small quantity of silica sand into a heated vessel so that the temperature will just about fuse the sand. It will melt and run together into a solid mass. There is another reason for the use of coal dust, and that is that it will help materially to vent the mould and allow the gases to escape. Coal dust for facing sand should be made from the best quality of soft or bituminous coal, containing neither slate nor phosphorus, but high in hydrocarbon gases and volatile matter, and the best gas coal makes the best dust for facing. This is the only kind of facing that is mixed with the sand. There are other facings, such as charcoal blacking, but these are either dusted on the mould or applied wet with a brush, as the class of work requires.

Decolorization of Carbolic Acid.—To decolorize the acid the following simple method, which if found reliable is sure to be largely employed, is recommended by the Pharm. Post. For purifying carbolic acid which had already become quite brown-red on account of having been kept in a tin vessel, the receptacle was exposed for a short time to a temperature of 25° C. (77° Fah.), thus causing only a part of the contents to melt. In this state the latter was put into glass funnels and left to stand for ten to twelve days in a room which was likewise kept at the above temperature. Clear white crystals formed from the drippings, which remained unchanged, protected from air and light, while by repeating the same process more clear crystals were obtained from the solidified dark colored mother lye. In this manner 75 to 80 per cent. of clear product is obtained altogether.

Deep Black Writing Ink from Logwood Extract.—Prepare a clear logwood extract solution by dissolving 200 parts of best French logwood extract in 1,000 parts of water by heating in a steam bath, place the solution aside to settle for about eight days and pour off clear from the accumulated deposit. Dissolve 200 logwood extract solution with 300 water, heat in a steam bath to about 90 C. (197° F.) and add drop by drop the following oxidation mixture prepared from 2 dichromate of potassium, 30 chrome alum and 10 oxalic acid dissolved in 150 water. Maintain the temperature for another half hour at 90° C. (197° F.), dilute with water to 1,000 total weight, add 1 per cent. carbolic acid, and allow to settle two or three days. Then express clear and fill in bottles.

Cementing Glass to Metal.—To glue glass to metal use the paste made by boiling together:

Resin	20	parts.
Soda	6	"
Potassium silicate	2 or 3	"
Water	22	"

A froth is obtained. This should be skimmed off and 50 parts of it mixed with 80 parts of plaster of Paris (gypsum).—La Science en Famille.

Cement for Caoutchouc.—The following method of repairing the cracks or fissures in articles of caoutchouc is given in the June number of L'Industrie Textile. First clean the surface of fissure or parts to be united very carefully and apply a cement composed of:

Sulphide of carbon	26	parts.
Gutta percha	2	"
Caoutchouc	4	"
Fish glue	1	"

The edges of the rent should be kept together by means of thread and the article left to dry. At the end of from twenty-four to thirty-six hours the binding thread may be removed and the cement which may have squeezed out of the fissure cut away.

Preserving Oil.—The turning rancid of oil is due to a superficial oxidation, which may be avoided by spreading over the oil a film of good whisky; this by its inferior specific weight is kept on the top of the oil, and effectually keeps the air from it. Bottles containing oil should, of course, be corked well, in addition to the above precautions being taken—La Vie Scientifique.

Blackening Aluminum.—A thoroughly good and practical way of blackening aluminum has until recently been unknown. The following, however, gives very good results: Polish the surface to be blackened with glass paper, then spread on it a thin film of olive oil, and heat slowly on a spirit flame. After a while the oil boils and takes a golden color. Then lay on another coat of oil, and heat strongly. The golden color becomes brown and soon darkens to an intense black. Let the article cool, wipe off the oil and let dry.—Cosmos.

FRANÇOIS' AIR COMPRESSOR AND ROCK DRILL.

Mr. Joseph François, of Seraing, whose name has been long known in connection with air compressing machinery, makes a fine display in the Machinery Hall of the Brussels Exhibition of compressors and rock drills. The former is illustrated by Figs. 4, 5 and 6. A special feature of this arrangement is that the springs controlling the movement of the air inlet valves are governed by a positive motion from the slide valve of the steam cylinder. It will be noticed that the clearance spaces at each end of the cylinder are reduced to insignificant dimensions, thus increasing the effective volume of air compressed with each stroke of the piston. This space is further reduced by the cold water admitted through the inlet valves for absorbing the heat developed during compression. This water flows freely into the cylinder to an amount of about two liters per cubic meter of air compressed. In the illustrations, A is the steam cylinder of the compressor; B is the air cylinder; C, the air inlet valves and the delivery valves; E F, the centers of the levers regulating the action of the springs closing the inlet valves; G is a single lever mounted on E and connected to an extension of the valve rod; H I are double levers mounted on the shaft, E F; T are the valve springs governed by the levers, H I; K is a connecting rod between H I. The following are some of the leading data of the compressor exhibited:

Diameter of steam cylinder....	12·60 in.
" air cylinder.........	11·81 "
Length of stroke................	19·69 "
Maximum speed........	60 revolutions.
Minimum "	5 "
Horse power developed with a speed of 60 revolutions per minute and an effective air compression to 71 lb. per square inch..........	25
Weight of air compressed per hour at a speed of 60 revolutions per minute	660 lb.

Two types of rock drills are also shown by the same exhibitor, and the smaller of these is illustrated by Figs. 1, 2 and 3, of which the perspective view gives a good idea of the general arrangement and Figs. 2 and 3 longitudinal and transverse sections. The drill is one of the smaller standard series, known as No. 7, because the diameter of its cylinder is 7 centimeters (2·76 in.) The general construction of the drill is that so well known by the names of the inventors, Dubois & François, but two special features are introduced to lessen the effect of shock on the mechanism at the end of each stroke. At the front end this is effected by means of a small safety cam, N, mounted in a recess on the guide of the piston rod, and of a rubber cushion, P, also in the recess, one end of the cam entering a recess in the rubber, while the other end can act on the spring, R, coupled to the valve, G. When the piston, B, strikes against the bottom of the cylinder, the cam is slightly and suddenly moved by a compression of the rubber pad produced by the shock, and the spring being released prevents the valve, G, from closing, and the air pressure immediately checks all further movement. At the opposite end of the cylinder a small auxiliary piston is placed, the rear face of which is constantly under pressure by means of a small passage leading from the valve chest, and, when the piston is driven back at the end of the stroke, the air serves as a cushion. Referring to the reference letters on the section, A is the drill cylinder; B, the piston rod coupling the drill; C, the slide valve; D, D', two pistons of different diameters; E, the valve chamber; F, a lever opening the valve, G, which is the air exhaust; H, the ratchet wheel for turning the drill; J, a guide for supporting the piston rod; L is a feed screw for advanc-

RIGHT AND LEFT HANDED ARMATURE WINDING.

By C. C. Hawkins, M.A.

Although the question of the "hand" of an armature winding may appear an easy one, and the rules

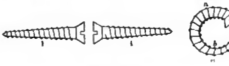

Fig. 1.—R.

which determine it are indeed simple, yet in the office or workshop these rules may have to be applied instantly and with certainty to somewhat complicated cases, and this is apt to be a perplexing matter unless the governing principles are thoroughly understood. The "hand" of a screw, by reason of which the movements of rotation and translation are connected together in two definite ways, is a fundamental fact of mechanics familiar to all. Further, a coil wound in an orderly manner round an axis presents so evidently a true analogy to a screw thread that the same difference

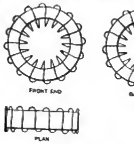

Fig. 2.—R.

between a right handed and left handed direction of winding is immediately recognized. But in the case of the armatures of continuous current dynamos, two separate questions may arise, and the distinction between the two is not always made sufficiently clear to students. Every armature consists of a number of loops, or of coils composed of many loops, connected together into a system by joining the end of one to the beginning of the next. Thus we may ask: What is the "hand" upon which the loops or coils of the armature are wound? And this ends the matter with alternators. But with continuous current armatures we may also ask a second question, viz.: What is the "hand" of the system on which the separate coils or

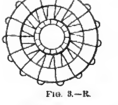

Fig. 3.—R.

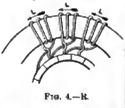

Fig. 4.—R.

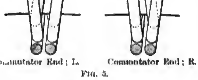
sections are connected together? The screw analogy is then applied, not only to the actual winding of the coils, but also by a further extension to their system of connection. Upon the first question depends the direction in which with a given field and rotation the induced potential rises in each coil; upon the second, the general direction in which the potential rises in the armature as a whole. As a rule, the hand of the system is the same with the hand of the coils, but this is not always and necessarily so, as is amply proved by the fact that in certain cases the actual loops have no



Commutator End; L. Commutator End; R.

Fig. 5.

hand at all; yet in such cases the system still has a "hand" assigned to it by analogy and conventional agreement.

The most convenient formula by which to test the "hand" of an armature coil is the following: "If in any helix with its axis placed horizontally an observer starts from the upper portion of a loop, and traces it toward himself and thence onward, he will be led to another loop further to his right if the helix be right handed, or further to the left if the helix be left handed (Rule I)." A right handed screw is a right handed screw, however we look at it, so that it is a matter of indifference whether we are standing on one side or the other when we apply the formula (cf. i and ii, Fig. 1); or, if the same be coiled into a ring, the observer may start from either the outside or inside of the ring so long as it is always the upper portion of a loop (e. g., in iii, Fig. 1, either from a or b) from which he commences to trace the thread toward himself. But the important corollary to be deduced from the circular screw when viewed from the side (as in Fig. 1, iii) is that if we start from any part of the thread on the out-

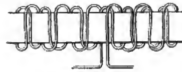


Fig. 6.—R.

side of the circle and trace it toward our point of view, we pass round the circle in a clockwise direction if the thread be right handed, and in a counter clockwise direction if it be left handed. This corollary will be found to furnish the criterion by which the second of our two questions is answered.

In the continuous current ring or discoidal ring armature, if each section of the winding as marked by the commutator segments is a simple loop, the "hand" of the loops and the hand of the system as a whole are one and the same question, and the answer to the one must necessarily be the answer to the other. The loops combine into a simple helix (Fig. 2) and our first rule is immediately applicable. It is immaterial at which end of the armature we stand, or where the commutator segments may be placed. If the commutator be formed by the external portions of the loops, as in some Continental multipolar machines, then, in applying Rule I, we start from a segment and trace it toward ourselves, and thence through the interior of the ring.

Fig. 7

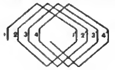

Fig. 8.

If the commutator is not arranged on the external periphery, then, when we start from any external wire and trace it toward ourselves, we are led to a segment and thence onward round the commutator in a clockwise direction if the winding be right handed as before. It makes no difference at which end we stand—e. g., in Fig. 3 the commutator might be at either end or centrally situated in the interior. But in the ordinary armature where the commutator is at one end, if we start from a commutator segment we must fix the direction of tracing with reference to the end at which we stand. It is simplest to consider the armature from the commutator end, and our second rule therefore takes the following form for ring armatures: "With a commutator at one end and standing at that end, if we start from a commutator segment and trace the winding away from our point of view through the interior of the ring, we pass round the segments in a clockwise direction if the

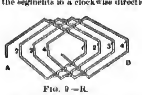

Fig. 9.—R.

armature system be right handed, or in a counter clockwise direction if it be left handed (Rule II A)."

If in a ring armature each section is composed of several loops in one layer on the outside, the hand of the system should be the same as the hand of the coils. It need not be so, as shown by Fig. 4, where the direction of each coil of three loops is left handed, while the general system is right handed. The winding then progresses round the armature in one direction while the coils themselves progress backward against this direction, and, in consequence, the commutator connections unnecessarily cross the width of the coil. Further, if the coils are in the same field, and the general direction of the rise of potential round the commutator or armature is shown by the large arrow (Fig. 4), the rise of potential in each coil is in the opposite direction, as shown by the small arrows; hence the difference of potential between adjacent turns is a maximum and

Side B turned up.

Fig. 10.

Side A turned up.

Fig. 11.

equal to twice that of one coil, which is a disadvantage. Thus, the arrangement of Fig. 4 would not practically be used, but it serves to illustrate how the system has metaphorically a "hand," no matter what may be the hand of the separate coils. We require to know the general direction of the current into or out of the brushes, and this is determined by the system of connection. In order, then, to find the conventional hand of the system, all that we have to do is to stand at the commutator end and trace the winding through the interior of the ring away from our point of view; we then pass from segment to segment round the commutator in a clockwise direction if the system is right handed. We need only follow one loop in each coil, and by so doing we virtually describe an imaginary helix as it were on the top of the real coils, and according to the hand of this helix the armature is right or left handed. Thus, if we follow one loop out of each set of three in Fig. 4, we in effect describe upon the actual coils the right handed helix of Fig. 3.

If in each section of a ring armature the turns are to be arranged in more than one layer, and the coil has a width of more than one turn, it is usual to commence

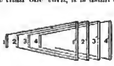

Fig. 12.—R.

winding the coil at or near the center of the total length of wire in the coil, so as to bring both the free ends to the outside layer. Under these circumstances the hand of the system should be the same as the hand of the bottom layer, since this avoids unnecessary crossing of the width of the coil by the commutator connections. The minimum number of turns per section which come under this rule is three, as seen in Fig. 5, which shows two such sections; the hand upon which the system is connected up should then be the same as that of the coil which has a lower layer of two turns, i. e., coil, A A, in Fig. 5. This coil, A A, must be wound first, so that if the armature is to be right handed we must start to wind from the right, and if left handed from the left. With a larger number of turns per section, the layers of each section are alternately right and left handedly wound; if the number of layers on the outside be two or any even number, the ends fall in the center of the coil (Fig. 6), while if the layers be three or any uneven number, they come to the outside edges, but in all

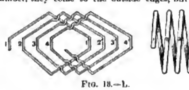

Fig. 13.—L.

cases the sections should be connected up with the same hand as that of the bottom layer of each coil.

Just as a watch spring may be coiled up in a clockwise or counter clockwise direction, but has no hand until its inner end is pushed or pulled through it, so a flat coil such as might form part of the armature of a disk alternator (Fig. 7) has by itself no hand. In exactly the same way, from the mere representation of a coil on the flat, such as Fig. 8, we cannot find out the hand; we must know which wires are underneath and which lie on the top where they cross one another. Fig. 8 may thus stand for three distinct cases. First, let the wires to the right lie above those to the left, as indicated in Fig. 9 by the small overarching half circles at each end. The winding is then right handed, as our fundamental rule will show. If we imagine a core to be passed through the loops as they are situated in Fig. 9, the wires on the side, B, will be at the top (Fig. 10) in the same order as in Fig. 9. Starting, then, from the upper portion of any loop, such as 1, and tracing it toward our point of view, we are led on to another wire, 2, which is further to our right. If side, A, be brought up to the top, as in Fig. 11, the wires will run toward the right in the order 4, 3, 2, 1—the reverse of Fig. 9—and again by Rule I, the winding is seen to be right handed. When Fig. 9 is translated into the long and short bars of an ordinary drum armature, with end connectors, 1' 2' 3' 4' must be the long bars, since they cross over the end connectors, and we thus get Fig. 12. In order to test the hand of such a diagrammatic winding by our first rule, we must start from a long bar on the top of the armature, and trace it toward our point of view. To start from a short bar on the top of the armature is tantamount to starting from the lower portion of a loop in a ring armature, instead of the upper portion.

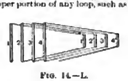

Fig. 14.—L.

Secondly, the wires to the left of Fig. 8 may lie above those to the right. We then get Figs. 13 and 14, which

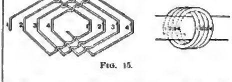

Fig. 15.

are the exact reverse of Figs. 9 and 12, and the winding is left handed.

A third case still remains, in Fig. 8. Let the wires to the right lie above those to the left at one end of the armature and below them at the other end. We thus get in Fig. 15 a combination of half of Figs. 9 and 13, and the winding of the loop has no hand at all. If a core be inserted through the loop as shown at the side of Fig. 15, it is seen that the winding is not a helix but an involved knot; yet it forms a perfectly valid drum winding. When translated into a bar armature with

end connectors, the bars are of the same length (Fig. 16), but set so that at each end of the completed armature alternate bars project, and the same bar does not project at both ends.

If a drum armature has only one loop in each section, and is wound as in Fig. 9 or Fig. 13, it is right handed in the first case and left handed in the second case, the hand of the system being necessarily the hand on which the loops themselves are wound. If a commutator is connected to the junctions at either end of Fig. 9, let us start to trace the winding from a segment, when standing at the commutator end; then if we proceed away from our starting point down a wire that forms one of the lower set leading away from the commutator, we pass round the commutator in a clockwise direction. Contrariwise, if a commutator be connected to either end of Fig. 13, and, standing at the commutator end, we proceed away from the commutator down one of

FIG. 16.

the lower layers of wire, we pass round the segments in a counter clockwise direction. Our second rule therefore takes the following form in drum armatures: "Standing at the commutator end, if we start from a commutator segment and trace the winding away from our point of view down the lower arm of a loop and so round to the next segment, we pass round the commutator in a clockwise direction if the armature be right handed, or in a counter clockwise direction if it be left handed (Rule IIB)." The condition "down the lower arm of a loop" is the counterpart of the condition "through the interior of the ring" in the case of ring armatures. In a bipolar armature the lower arm of a loop evidently leads away to the under side of the core which we imagined to be threaded through the loops as they are shown in Figs. 9 and 13, and the analogy is clear, although it is not so evident in multipolar drums, where the coils are comparatively flat. If the winding is composed of bars and end connectors and the commutator is attached to the ends of the long bars, the rule becomes even simpler; we must always proceed away from the segment which forms our starting point down an end connector, and not down a bar. It is quite immaterial on which side of the shaft any connector passes, except so far as the length of an end connector is affected. If the commutator is attached to the center of evolute end connectors, then as we pass down a segment we come to the two arms of the connector, one of which forms part of the outer whorl of spirals and the other part of the inner whorl; in this case, we must always proceed down the arm which is in the inner set of spirals next to the armature core, and so to the end of a short bar.

In the case of Fig. 15 all the above holds equally good; but now, since the loops have no hand, we are dealing simply with the metaphorical "hand" which is conventionally assigned to the system. In this case the hand of the system varies with the end of the armature to which the commutator is attached, since the bars which project at one end do not project at the other end.

Fig. 17 shows that in all cases, if we pass round the segments by Rule IIB, in a clockwise direction, we are virtually describing on the actual loops a right handed

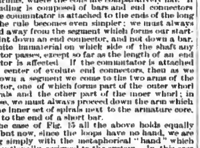

FIG. 17.—R.

spiral, and, as far as the question of the system is concerned, it is quite immaterial, not only on which side of the shaft the end connectors pass, but whether any bar at the far end projects or does not project.

If each section of the drum armature has several loops, these may be wound according to either Figs. 9 or 13, and the hand of the system should then follow the hand of the loops, for the same reasons as in a ring armature. Fig. 15 would not be a practical method for a wire wound armature with several loops per section, but is perfectly feasible with a bar wound armature, and in this case the hand of the armature is fixed according to the end at which the commutator is attached.

In single phase alternators the coils are, as a general rule, alternately right and left handed, although whether this is so depends entirely upon what is the most convenient method of joining together the separate sections. In any case the system, as a whole, has no hand, since the coils do not unite into a spiral.—The Electrician, London.

ART AND NATURE IN LANDSCAPE GARDENING.

IN the spring we receive the most frequent inquiries from amateur planters about shrubs, trees and herbs for what they call "decorative planting." Many persons who have acquired new homes in the country or in the suburbs of cities are moved to beautify them in some way, and the first thought that occurs to every one is to secure an abundance and variety of what are known as "ornamental" plants. It is not our purpose to make out any such list, and even if we considered it advisable, the season is too far advanced to begin to arrange for planting. Nevertheless, these requests suggest a word or two of counsel which may as well be repeated at one season as another. We have no novel doctrine to advance, nothing but a few principles which do not change every year like fashions in millinery.

The spring planting of trees and shrubs is practically over for the year, and where these have been planted by novices it is probable that they have been badly selected and planted in improper positions. Nevertheless, this fact is not utterly discouraging, for when once a land owner begins to take any serious interest in his home grounds it is probable that the habit will grow on him and become a lifelong and increasing source of refreshment and refinement. We have said that both planning and planting by novices are, as a rule, worse than unsatisfactory, for if there is any art which needs original aptitude, special training and long experience for the highest success, it is the art of planting public and private grounds. This statement will be admitted by most men of cultivation, but practically they do not realize its truth. An engineer or a botanist is considered qualified to plan a public garden. Places of remarkable natural beauty, when once they are acquired by a city, are often put under the control of commissioners, who may have a fair education and experience in business, and if they have in addition to this what is known as good taste they are esteemed perfectly competent to preserve the scenes, to develop their charms and to devise facilities for exhibiting them. Gentlemen of wealth who have some cultivation consider themselves quite able to lay out their own places, especially if they have the help of some journeyman gardener, who often has no appreciation of the character and beauty of the grounds, and whose first work will be to despoil the scenery of all that makes it really valuable, and then begin the work of decorating it with flower beds, golden elders and purple-leaved shrubs of various kinds. The worst part of the matter is that the men who are utterly lacking in their ability to foresee what a piece of ground will look like a few years after they have set out to "improve" it, are quite unconscious of their lack of qualification, and have not the slightest idea that any such qualification is needed. Even if they were capable of taking such a look into the future, they would not be competent to pass any intelligent judgment on the result of their work. The fact is that no one but a man of genuine creative faculty can see just what elements in a landscape are the essentials that ought to fix its character, or can estimate the relative proportional importance which should be given to each one so as to produce the best combined effect and invest the whole with a charm which is distinctly its own.

This brings us again to the point that for the treatment of any piece of ground, public or private, the counsel of a landscape gardener of recognized standing should be at once taken. The novice who insists upon improving his own grounds must educate himself through his own mistakes. If he begins at the wrong end and buys a great many more novelties and oddities among trees and shrubs than he needs, and then wanders around in his lot for a place to plant them, he will soon see that his crowded grounds have no unity of expression or of purpose. If, however, he will endeavor to set before his mind a clear and definite picture of what his house and grounds together are to look like, and will then attempt to construct his picture, he will not be led to choose a plant simply because the catalogue pronounces it beautiful, but because it is necessary to complete his idea and give expression to his thought. All this sounds very simple, but he will find it no easy task to create such a picture even in imagination. But if he has in mind a design which is reasonably distinct, and for the details of which he can give intelligent reasons, he will certainly learn some things by his experience which very few of his fellow men understand. When he studies his house and grounds not only as a unit, but in their relation to what is beyond them, and endeavors to shut out what is distracting or unsightly and preserves within a fitting framework the view of distant prospects that are pleasing, and when he attempts to provide for conveniences in the way of buildings and walks and place them so that they do not disturb his picture, he will learn that it requires not only taste, but hard study, to solve the complex problem that he has in hand. He will learn, too, that even within the modest limits of his home acre there are chances for an individuality of plan and for a refinement and finish in the details which an artist of the first rank would not deem unworthy of his powers.

The objection is sometimes made to the work of artists in landscape that, after all, purely natural scenery is the most impressive, and the art of man can only interfere with nature to belittle it or weaken its strongest effects. But the true artist aims to help, and not to hinder nature. Even the broadest landscape can be improved, that is, adapted to human use and enjoyment, if it is treated in a reverent spirit. We do not attempt to thwart nature when we open her thickets and help magnificent trees in their development. We are working with nature if we encourage a screen of foliage deep enough to exclude the intrusion of some disagreeable object, or if we open vistas which will uncover to us the sky line made by a mountain range. Nature alone does not spread out for us broad stretches of meadow, but if we come to her aid she will give to us all the turf we need. That is, the real artist emphasizes and intensifies here or subdues and qualifies there. He uses the art that mends nature, working in harmony with, and not against her. The truth is not thoroughly comprehended by persons who consider the true work of the landscape gardener to be the planting of flower beds and of ornamental shrubs. But, after all, it is this broad and catholic art which alone is satisfying everywhere, and which is just as useful in the preservation of the Yosemite Valley or the scenery of Niagara as it is in planning a pastoral park or the grounds about a country house.—Garden and Forest.

ON THE ASCENT OF WATER IN TREES.*

WITHIN the last few years the problem of the ascent of water has entered on a new stage of existence. The researches which have led to this new development are of such weight and extent that they might alone occupy our time. It will be necessary, therefore, to avoid, as far as possible, going into ancient history. But it will conduce to clearness to recall some of the main stepping stones in the progress of the subject.

The two questions to be considered are: (1) What is the path of the ascending water? (2) What are the forces which produce the rise?

(1) The first question has gone through curious vicissitudes. The majority of earlier writers assumed that the water traveled in the vessels. This was not, however, a uniform view. Cæsalpinus, 1583, seems (Sachs' "History of Botany," English Trans., p. 451) to have thought that water moved by imbibition in the nerves. Malpighi and Ray held that the vessels serve for air and the wood fibers for the ascent of water. Hales ("Vegetable Staticks," p. 130), who believed in the sap vessels as conduits, speculated on the passage upward of water between the wood and the bark. Also (loc. cit., p. 19) that water may travel as vapor not in the liquid state. In the present century, Treviranus (Sachs' "History"), 1835, held that water traveled in vessels; De Candolle, 1832, that the intercellular spaces were the conduits. In Balfour's "Manual of Botany," 1863, vessels, cells and intercellular spaces are spoken of as transmitting the ascending water.

The change in botanical opinion was introduced by the great authority of Sachs,* who took up Unger's view† that the transpiration current travels in the thickness of the walls as water of imbibition.

Then followed the reaction against the imbibitionists—a reaction which has maintained its position up to the present time. Boehm, who had never adopted the imbibition theory, must have the credit of initiating this change; his style was confused and his argument marred by many faults, but the reaction should in fairness be considered as a conversion to his views, as far as the path of the traveling water is concerned. Nevertheless, it was the work of others who principally forced the change on botanists, e. g., Von Höhnel (Pringsheim's Jahrb., xii, 1879), Elfving (Bot. Zeitung, 1882), Russow (Bot. Centr., xiii, 1883), R. Hartig ("Ueber die Vertheilung," etc., Untersuchungen aus dem Forst. Bot. Inst. zu München, ii and iii), Vesque (Ann. Sc. Nat., xv, p. 5, 1883), Godlewski (Pringsheim's Jahrb., xv, 1884), and others.

(2) The second question has a curious history and one that is not particularly creditable to botanists generally. It has been characterized by loose reasoning, vagueness as to physical laws and a general tendency to avoid the problem, and to scramble round it in a mist of vis à tergo, capillarity, Jamin chains, osmosis and barometric pressure.

An exception to this accusation (to which I personally plead guilty) is to be found in Sachs' imbibition theory, in which, at any rate, the barometric errors were avoided, though it has difficulties of its own, as Elfving has pointed out.

But the most hopeful change in botanical speculation began with those naturalists who, concluding that no purely physical causes could account for the facts, invoked the help of the living elements in the wood. To Westermaier (Deutsch Bot. Ges., Bd. i, 1883, p. 371) and Godlewski (Pringsheim's Jahrb., xv, 1884) is due the credit of this notable advance, for whether future research uphold or destroy their conclusions, it claims our sympathy as a serious facing of the problem by an ingenious and rational hypothesis.‡

We may pass over the cloud which arose to witness for and against these theories and proceed at once to Strasburger's great work (Leitungsbahnen, 1891), in which, with wonderful courage and with the industry of genius, he set himself to work out the problem de novo, both anatomically and physiologically. In my opinion it is difficult to praise too highly this great effort of Strasburger's.

Strasburger's general conclusion is now well known. He convinced himself that liquid can be raised to heights greater than that of the barometric column in cut stems, in which the living elements have been killed. Therefore, the cause of the rise could not be (1) barometric pressure, (2) nor root pressure, (3) nor could it be due to the action of the living elements of the wood. His conclusions may be stated as follows:

(a) The ascent of water is not dependent on living elements, but is a purely physical phenomenon.

(b) None of the physical explanations hitherto made are sufficient to account for the facts.

Strasburger has been most unjustly depreciated, because his book ends in this confession of ignorance. I do not share such a view. I think to establish such distinct, though negative, conclusions would be, in this most nebulous of subjects, an advance of great value. Whether he has established these conclusions must of course be a matter of opinion. To discuss them both would be to go over 300 pages of Strasburger's book, and will not here be attempted. Conclusion (a) that the ascent is not dependent on living elements must, however briefly, be discussed, because it is here that the roads divide. If we agree with Strasburger, we know that we must seek along the physical line; if we differ from him, we are bound to seek for the missing evidence of the action of the living elements.

Schwendener's Criticism.—Perhaps the best plan will be to consider the most serious criticism that has been published of Strasburger's work, namely, Schwendener's paper "Zur Kritik," etc. (K. Preuss. Akad., 1892, p. 911.)

Schwendener objects that although a continuous column of water cannot be raised by air pressure to a greater height than that of the barometric column, yet when broken into a number of columns, as in the case of a Jamin chain, that a column considerably over 10 m., even as much as 13 or 14 m., of water can be suspended. This, though not fatal to Strasburger's conclusions, is no doubt a serious criticism. For if 13 m. can be supported, some of Strasburger's experiments are inconclusive. He finds that a branch can suck up a poisonous fluid to over 10 m., and, as above explained, argues that all ascent above that height, not being due to barometric pressure or to the living elements (since the wood is poisoned), is for the present inexplicable. But, if Schwendener is right, the effect above 10 m. may have been due to atmospheric pressure. Askenasy (loc. cit. infra, 1895, p. 6) objects to Schwendener that the supposed action cannot be continuous. By repeating the diminution of air pressure at the upper end, the movement of water becomes less

* A paper read before Section K of the British Association at the Liverpool meeting, by Francis Darwin, F.R.S. (Revised January 20, 1897.)—From Nature.

* Physiol. Végétale (French Trans.), 1868, p. 225, and more fully in the Lehrbuch. Sachs also partially entertained Quincke's well-known suggestion of movement of a film of water on the surface of vessels.

† Sitz. k.k. Akad. Wien, 1868. Dixon's and Joly's paper in the Annals of Botany, September, 1895, gives evidence in favor of a certain amount of movement of the imbibed water.

‡ It is of interest to note that Hales, in speaking of the pressure which he found to exist in bleeding trees, says: "This force is not from the root only, but must also proceed from some power in the stem and branches." ("Veg. Staticks," 127, p. 110.)

and less, and sinks to almost nothing. Askenasy adds, moreover, that the amount of water which could be raised according to Schwendener's theory would be very small.

One difficulty about Schwendener's theory is that the result depends on the length of the elements of which the chain is made up (each element being a water column plus an air bubble). In his paper, "Ueber das Saftsteigen" (K. Preuss. Akad., 1886, p. 561), he finds that the elements of the chain in Fagus equal in round numbers 0·5 mm. In his paper (K. Preuss. Akad. Sitz., 1893, p. 842), "Wasserbewegung in der Jamin'schen Kette," he finds the element in Acer pseudo-platanus = 0·9 mm., in Acer platanoides and Ulmus effusa = 0·2. But the calculation (1892, p. 934) is based on the existence of a chain in which the water columns are each 10 mm. in length, a condition of things which he allows does not occur in living trees.

But even if we allow Schwendener to prove theoretically the possibility of a Jamin chain being raised to a height much greater than that of a barometric column, I do not think he invalidates Strasburger's position. Schwendener's idea necessitates the traveling of a Jamin chain as a whole, i. e., the translation not only of water, but of air bubbles. But this cannot (as Strasburger points out) apply to his experiments on conifers, in which the movement of air to such an extent is impossible ("Ueber das Saftsteigen," Hist. Beiträge, v, 1893, p. 50). And for the case of dicotyledonous woods, Strasburger has shown that the movement of air is excluded by the fact that transverse walls occur in the vessels at comparatively short distances. In Aristolochia the sections may be as long as 3 m., but in ordinary woods, according to Adler (as quoted by Strasburger), we get: Alnus, 6 cm.; Corylus, 11 cm.; Betula, 12 cm.; Quercus, 57 cm.; Robinia, 69 cm. These facts seem impossible to reconcile with Schwendener's views.

Action of the Poisonous Fluids in Strasburger's Experiments.—The question whether the living elements are killed in Strasburger's experiments is of primary importance in the problem.

Schwendener does not criticise it at length; he seems to assume (Zur Kritik, loc. cit., 1892, p. 935)—as far as I can understand—that since the death of the tissues extends gradually from the cut end upward, there are living cells in the upper part which may still be effective. He also doubts "whether the cells were always killed at once." The first objection of Schwendener's may or may not be sound, but in any case it does not (as Strasburger points out) account for the experiment (Hist. Beitr., v, p. 12) in which an oak stem was poisoned by picric acid, and three days afterward was placed in fuchsin picric. The second reagent had to travel in tissues already killed with picric acid, yet a height of 22 m. was reached.

The question whether the reagents kill the cells in Strasburger's experiments does not lend itself to discussion. It is difficult to see how they should escape, and we have Strasburger's direct statement that the living tissues were visibly killed. It must not be forgotten that, in some of his experiments, the death of the tissues was produced by prolonged boiling, not by poisons (Leitungsbahnen, p. 646). Thus the lower 12 m. of a Wistaria stem were killed in this way, yet liquid was sucked up to a height of 108 cm. In the Histolog. Beitr., v, p. 64, he has repeated his air pump experiment, using a boiled yew branch, and found that eosin was sucked up from a vessel in which almost complete vacuum was established; so the action of living elements and of atmospheric pressure was excluded.

On the whole, the balance of evidence is, in my judgment, against the belief that the living elements are necessary for the rise of water. In other words, I think we should be justified, from Strasburger's work, in seeking the cause of ascent in the action of purely physical laws.

Strasburger's General Argument from the Structure of Wood.—It seems sometimes to be forgotten that, apart from the physiological or experimental evidence, there is another line of argument founded on the structure of wood. Strasburger's unrivaled knowledge allows him to use this argument with authority, and he seems to me to use it with effect. Thus (Hist. Beitr., v, p. 17) he points out that though in coniferous wood the action of the living elements in pumping water is conceivable, yet this is far from being universally the case. He points out that in the monocotyledons such theories meet with almost unconquerable difficulties. This is, he says, especially the case in Dracæna. He goes on to point to difficulties in the case of such dicotyledons as Albizzia. The case may perhaps best be put in the generalized manner that Strasburger himself employs (loc. cit., p. 20). If the living elements are of such importance as Godlewski, Westermaier and Schwendener hold, we ought not to find these difficulties; we ought rather to find structural peculiarities pointing distinctly to the existence of such functions. For instance, we ought to find the tracheal water path actually interrupted by living elements which might act like a series of pumping stations one above the other. It should, however, be remembered that if we deny the importance of the medullary rays and other living elements in raising water, we ought to be able to point more clearly than we can at present to the function of the medullary rays and to structural adaptations to these functions.

The Work of Dixon and Joly and of Askenasy.—I now pass on to the recent work in which Strasburger's indications to search along a purely physical line have been followed. In the paper of Dixon and Joly (Proc. Roy. Soc., vol. lvii, 1894, No. 340) the suggestion was for the first time made that the raising of water to the tops of trees depends on the quality which water possesses of resisting tensile stress. To most botanists the existence of this quality is a new idea. To believe that columns of water should hang in the tracheals like solid bodies, and should, like them, transmit downward the pull exerted on them at their upper ends by the transpiring leaves, is to some of us equivalent to believing in ropes of sand. The idea is more fully treated in the Phil. Trans., vol. clxxxvi, and in the Annals of Botany, vol. viii. The same leading idea occurred independently to Askenasy, who has published it in the Verhand. d. naturhist. med. Vereins Heidelberg, N. F., Bd. v, 1895, and N. F., Bd. v, 1896.

Askenasy has earned the gratitude of his botanical readers by giving some of the evidence which demonstrates the existence of this property of water.* A tube a meter in length was filled by Donny with water, and the remaining space was as far as possible freed from air. When the tube was placed vertically, the water column at the upper end hung there and could not be made to break or free itself from the glass by violent shaking. Berthelot filled a thick wall capillary tube completely with water at 28°-30° C.; it was allowed to cool to 18°, so that the space left by the shrinking of water was filled with air. It was then sealed up and again warmed to 28°-30°, so that the air was dissolved in the water. When it was allowed to cool again it retained its volume, filling the tube completely. A slight shake, however, allowed the water to break and return to its proper volume at 18° with the appearance of a bubble of air. In this experiment the water contained air, yet it seems to have been until recently assumed by some physicists that to show cohesion, water must be air free. If this were the case, the application of the principle to plants would be impossible. Dixon and Joly have, however, proved that this is not so, and this forms an important part of their contribution to the subject.

They also † investigated the amount of tension which water under these circumstances will bear, and found it about equal to seven atmospheres. If, therefore, the leaves at the top of a tall tree can exert the requisite upward pull on the water in the trunk, it seems certain (if no other condition in the problem interfere) that the pull can be transmitted to the level of the ground. This opens up the question whether the leaves can exert this traction on the water in the tracheals, and what is equally important, are there any factors in the problem incompatible with the theory?

(1) The Sucking Force of the Leaves.—In Dixon and Joly's first paper (Phil. Trans., pp. 563, 565) they assume that tractional force is given by the menisceses "formed in the membranous réseau of the evaporating cell walls," as well as possibly by the osmotic action of the cells of the mesophyl. We shall take these theories in order. Our knowledge of the cell wall does not allow us to believe in the existence of pores visible with even the highest powers of the microscope. Dixon's more general expression (Proc. Roy. Irish Acad., Jan. 13, 1896, p. 767), "surface tension forces developed in the substance of the walls of the evaporating cells," is therefore preferable. But Askenasy seems to me to state the matter much more conveniently by using the term "imbibition" (loc. cit., 1895, p. 10). The force with which vegetable membranes, e. g., the thallus of Laminaria, absorb water has been demonstrated by Reinke and others, and the existence of such a force is familiar to botanists.

Both Askenasy (loc. cit.) and Dixon and Joly (Annals of Bot., September, 1895) have pointed out that the force of imbibition, or the surface tension forces, as the case may be, can exert a tractional effect on the water in the tracheals, when the turgescence of the mesophyl has been destroyed. But Askenasy in his original paper (1895), Dixon in the January, 1896, paper, and again Askenasy in his second paper (March, 1896) have also considered the imbibitional or surface tension forces in connection with the turgescent cell. It must clearly be understood that this does not remove imbibition from the problem. The sun's heat causes the evaporation of the water with which the walls of the mesophyl cells are imbibed; this water is replaced by imbibition from the cell sap. The concentration of the cell sap so produced maintains the osmotic force of the cell, which again exerts suction on the water on the tracheals.‡

I have now given, in its simplest form, the modern theory of the rise of water. Apart from the main idea, it combines the points of several familiar views. Imbibition becomes a factor of paramount importance, though not in the way that Sachs employs it. The suspended threads of water remind us of Elfving's capillary theory, while the living element factor is represented by the turgescent mesophyl cells.

Resistance.—It is not possible to discuss the question whether the tractional forces in the leaf are sufficient for the work imposed on them until we know what is the resistance to the passage of water through wood. For it is clear that the work done by the leaf includes not only the lifting of a given column, but the overcoming of the resistance to its flow.

The resistance to the flow of the transpiration current is in want of farther investigation. Janse (Pringsheim's Jahrb., xvii, 1887, p. 1) has discussed the question, and points out (loc. cit., p. 36) that two kinds of resistance must be reckoned with. The first (which he calls statical) is illustrated by means of a cylinder of Pinus wood fixed to the short arm of a J tube filled with water, when it was found that in five days the level of water in the long arm was only 1 mm. above that in the short arm.§ That is to say, when time enough is given, the resistance is practically nothing. Janse has also investigated the resistance to the passage of water flowing through wood at the rate of an ordinary transpiration current. His method seems to me open to criticism, but this is not the place to give my reasons. His experiments give a wide range of results. With Pinus strobus a pressure of water equal to ten times the length of the wood was required to force water through at a pace equal to the transpiration current. In Ginkgo the pressure was twenty-one times the length of the wood. Strasburger (Leitungsbahnen, p. 779) has repeated Janse's experiment, and finds a column "several times the length of the object" necessary. Nägeli ("Das Mikroskop," 2d edit., p. 385) found that 760 mm. of mercury were needed to force water through fresh coniferous wood at the rate of 1/10 mm. per second, i. e., at 180 mm. per hour. If we allow one meter per hour as a fair transpiration rate (Sachs' "Arbeiten," ii, p. 182), we get a pressure of 5 atmospheres required to produce such a flow. To return to Janse's experiments: even if we assume that the resistance (expressed in water) = 5 times the length, it is clear that with a tree 40 m. in height the resistance of 20 atmospheres has to be overcome. This would not be a pressure greater than that which osmotic forces are able to exert, but when we come to a tree of 80 m. in height, and a resistance of 40 atmospheres, the thing becomes serious.* A great difficulty in the question of resistance is that the results hitherto obtained are (though here I speak doubtfully) much greater than those obtained by physicists for the resistance of water flowing in glass capillaries. Until this discrepancy is explained it is rash to argue from our present basis of knowledge.†

Is the Osmotic Suck Sufficient?—The osmotic force of a turgescent cell is usually measured by its power of producing hydrostatic pressure within the cell. Thus, De Vries ("Untersuchungen über d. mechanischen Ursachen der Zellstreckung," 1877, p. 118) investigated the force necessary to extend a plasmolyzed shoot to its original length; Westermaier (Deutsch. Bot. Ges., 1883, p. 382) the weight necessary to crush a tissue of given area; Pfeffer (Abh. k. Sächs. Ges., 1893) the pressure exerted by growing roots; Krabbe (K. Akad. Berlin (Abhandlungen), pp. 57, 69, 1884) the pressure under which cambium is capable of maintaining its growth.

The figures obtained by these naturalists have a wide range; it may be said that the hydrostatic pressure varies between three and twenty atmospheres.

Another method is to ascertain the osmotic strength of the cell sap in terms of a KNO_3 solution, and calculate the pressure which such a solution can produce. According to Pfeffer (Pfeffer, Phys., i, p. 53), 1 per cent. KNO_3 with artificial membrane gives a pressure of 176 cm. = 2·3 atmospheres. De Vries (Pringsh. Jahrb., xiv, p. 527) calculates that in a cell a 0·1 equivalent solution (practically = 1 per cent.) gives a pressure of three atmospheres. We may, therefore, take it as between 2·3 and 3 atmospheres. Now, De Vries found that beetroot requires 6 to 7 per cent. KNO_3 to plasmolyze it; this would mean 15 to 21 atmospheres. I do not know what is the greatest pressure which has been estimated in this way. Probably Wieler's (Pringsh. Jahrb., xviii, p. 82) estimate of the pressure in the developing medullary ray cells of Pinus sylvestris at twenty-one atmospheres is the highest. It is clear that investigation of the osmotic capacity of leaves for high trees is wanted, also investigations of the variation in osmotic power produced by varying resistances in the flow of the current. The experiments of Pfeffer and others‡ show that the osmotic strength of cell sap is capable of great adaptation to circumstances—cells respond by increased turgescence to various stimuli. Whether they can respond sufficiently to account for the ascent of water is another question.

My own opinion is that the question of resistance to the flow of water is a difficulty which the authors of the modern theory have not sufficiently met. Unless it can be shown that the resistance to the flow of water in wood is less than that indicated by existing researches, we must face the fact that we do not at present know of osmotic forces which we can suppose capable of raising water to a greater height than forty meters.

Continuity of the Water in the Tracheals.—The theory we are considering apparently requires that there shall be continuous columns of water from leaf to root, because a break in the column means a collapse of the machinery. This seems at first sight a fair assumption, though I doubt its complete correctness. It is in any case worthy of discussion. It has been constantly insisted on by Sachs and others that at the time of most active transpiration the vessels contain air, and not water. It is, therefore, a violent disturbance of our current views to believe in continuous columns of water.

For evidence on this point we are chiefly indebted to Strasburger. It is a remarkable fact that he should, without any theory to encourage such a view, have come to the conclusion that approximate continuity of water columns is a condition of primary importance, and that he should have made out the cognate fact that the whole of the alburnum need not be simultaneously occupied by a transpiration current; parts of it may be so occupied, while parts of it are filled with air, and do not function as waterways. This is a valuable contribution to knowledge, and to the adherents of the new theory it is priceless; the very existence of their hypothesis may depend on it.

Strasburger's statements and reasoning are by no means accepted by every one; for instance, Schwendener refuses to take them seriously (K. Preuss. Akad., 1892, p. 931).

Strasburger has microscopically examined the condition of the tracheals as regards air.§ He found in the spruce fir in July "almost no air bubbles" in the wood of the current year, but air in considerable quantity in four-year-old wood. In the same month Pinus Salzmanni (Laricio) showed scattered bubbles in the spring wood of last year, and more in the autumn wood. In a larch there were only very occasional bubbles in the two last years' wood. In the silver fir the current year's wood was practically free from air; the air increased in the inner rings. Tsuga canadensis had no air in this year's wood, only a little in last year's, and an increasing quantity in the older rings, the fifth being very rich in air. In February, Pinus strobus had hardly any air in this year's wood, and the silver fir was all but free from it in the youngest ring. Robinia in July had the youngest wood almost air-free. Ficus elastica and spuria, various acacias and willows gave vessels not entirely free from air, but nearly so. He concludes (loc. cit., p. 688) that the path of the transpiration current is not absolutely free from air. The younger wood, which especially functions as the water carrier, is the most free.

Dixon and Joly quote Strasburger's results, which they consider sufficiently favorable to their views. They rely, in addition, on the impermeability of wet cell walls to air, isolating the conduits in which air has appeared; and on the possibility that the air may be redissolved under root pressure (Phil. Trans., p. 572)—an idea well worth testing.

* He gives reference to Donny, Poggendorff's Annalen, 67 Bd. (143 Bd. d. g. R.), 1846, p. 562; Berthelot, Annales de Chimie et de Physique, S. 3, t. 30, 1850, p. 232; Worthington, Proc. Roy. Soc., vol. l, 1892, p. 423.

† Phil. Trans., vol. 186, p. 570. With ethyl alcohol Worthington records a tension of 17 atmospheres. See Proc. R. Soc., vol. l.

‡ Sachs' "Text Book," edit. iv., Eng. Tr., p. 679, describes evaporation taking place in the cell wall, which makes good the loss by imbibition.

§ Strasburger (Leitungsbahnen, p. 777) observed equilibrium established a good deal quicker.

* Schwendener's experiments, K. Preuss. Akad., 1886, p. 573, do not particularly bear on this question.

† It is possible that the rate of the ascending water is much less than is usually assumed. Thus Schwendener (K. Preuss. Akad., 1886, p. 584) calculates from an observation of v. Höhnel that the transpiration current in the stem of a tall beech was only 2 meters per day.

‡ Pfeffer, "Abhand. der k. Sächs." Ges., xx, p. 300; Eschenhagen, Untersuchungen aus d. Bot. Inst. z. Tübingen, 1889; Stange, Bot. Zeit., 1892.

§ Leitungsbahnen, p. 668 et seq.; Russow in 1883 (Bot. Centr., vol. xiii, 1883) observed similar facts in the distribution of water and air.

I think Strasburger's facts are not so favorable to their theory as these authors believe; in the same way it seems to me that Askenasy is rash in saying* that the tracheals in many cases contain continuous columns of water. It is true that this statement does not affect the validity of his general argument, since he faces the undoubted occurrence of air bubbles in many cases. This is undoubtedly necessary, and, fortunately, we can once more turn to the Leitungsbahnen. Strasburger states that he has seen water creep past the air bubbles (Leitungsbahnen, pp. 704, 709; see also "Hist. Beitr." v, p. 76) in coniferous tracheids. The best evidence for this seems to be the fact mentioned (ibid., p. 70), that the part of a single tracheid in front of an air bubble gets red, with absorbed eosin, though the neighboring tracheids are colorless. This clearly suggests the creeping round the bubble which Strasburger believes in. Schwendener (Zur. Kritik, etc., p. 921) has been unable to confirm Strasburger's microscopic observations, and, moreover, denies the physical possibility of the phenomena. I am unable to judge of the validity of Schwendener's theoretic objections, and must leave this point. It is a question of great importance whether it is possible that, on the breaking of a column of water, a film of water remains surrounding the air bubble, and capable of holding the two columns together. If this is impossible, we must suspend our judgment until we know more of the contents of the tracheals.

To sum up this part of the subject, we may believe that the tracheals in their youngest condition may contain water in continuous columns, since the cambium cells from which they arise certainly contain fluid. But we know also that this condition is not absolutely maintained, since Strasburger has shown that the young wood contains air, though in small quantity. We must, therefore, believe either (1) that the transpiration current is able to travel past the air bubbles, or (2) that tracheals partly filled with air may again become continuous waterways by solution of the air. If we adopt the first alternative, we must believe that the film of water between the bubble and the wall of the vessel is able to bear such a tensile stress that it can serve to link the column above with the column below the bubble. But this is analogous to trusting a rope so nearly cut through that only a few threads remain intact. With regard to the second alternative, we have, at least, indications from Strasburger's work that a tracheal partly filled with air does not necessarily remain permanently functionless (see Leitungsbahnen, p. 692).

The Isolation of the Tracheals.—There are a number of points connected with the structure and properties of wood which ought to be considered in relation to the modern theories. Want of space forbids my doing more than referring to two of them.

The resistance which the wetted cell wall offers to the passage of undissolved air is a point on which many writers have laid stress. It is clear that, on any theory of the movement of water in the tracheals, it is essential that air should not filter into the waterway. This necessity is not, however, stronger in the case of the modern theories we are considering. The pressure tending to fill the tracheals with air from outside cannot be greater than atmospheric pressure and since the wetted cell walls of gymnospermous wood can resist the passage of air under a pressure of about an atmosphere,† we need not fear criticism of the theory on this ground. The above remarks seem, however, to be needed in face of the frequently recurring statement that wet wood membranes are impermeable to free air. Schwendener had some good remarks on this head (Zur Kritik, p. 943).

Strasburger has called attention to the important subject of the localization or isolation of vessels, or of certain lines of tracheids. When this is possible we may have one set of tracheals containing continuous water columns, while neighboring ones contain air at negative pressure (see Histolog. Beiträge, v, p. 87). This is especially important in connection with the Dixon-Joly-Askenasy theory, since if there were no such isolation, a functioning tracheal containing a continuous column of water would give up its water to one which was not functioning. In other words, the inactive tracheals would, by negative pressure, suck water from the active ones. In the coniferous trees the young wood is cut off by the absence of pits in the tangential walls‡ from free communication with the older wood, where air is more frequent.

In the same way the valvelike closure of the pits by the aspiration of the pit membrane comes to be a subject of much importance.

At present I merely wish to show by a couple of examples the necessity of a complete study of the minute structure of wood in relation to the modern theories. It is, at least, a hopeful fact for Messrs. Dixon, Joly and Askenasy that we cannot point to anything in the anatomy of wood which is absolutely inconsistent with their views. Finally with regard to the question at large whether we are friends or opponents of Messrs. Dixon, Joly and Askenasy's theory, the broad facts remain that water has the power of resisting tensile strength, and that this fact must henceforth be a factor in the problem. There are difficulties in the way of our author's theory, but it is especially deserving of notice that many of these difficulties are equally serious in the case of any theory which excludes the help of the living elements of the wood, and assumes a flow of water in the tracheals. The authors have not only suggested a vera causa, but have done so without multiplying difficulties. There is, therefore, a distinct balance in their favor.

Huxley, quoting from Goethe, makes use of the expression thätige Skepsis. It is a frame of mind highly appropriate to us in the present juncture, if we interpret it to mean a state of doubt whose fruit is activity, and if we translate activity by experiment.

Among the metallurgical exhibits at the Scandinavian Exhibition, at present being held in Stockholm, there are some samples of steel billiard balls. These balls, which are made by a secret process out of Mitis cast steel, are hollow, and are claimed to be equal in all respects to ordinary billiard balls.

THE EAST INDIA FRONTIER TROUBLES.

WE present with this article several views of localities in those parts of British East India which have recently been disturbed by native risings.

One of these cuts shows a street in the city of Peshawur, itself at one time in danger of insurrection by its Oriental population. From here troops were sent to the aid of the garrison at Shabkadar, when a band of rebels nearly eight times superior in number to the English came very near forcing these to surrender.

THE INDIAN UPRISING—STREET IN PESHAWUR.

Another place of interest is shown in our fourth illustration. It is the Khyber Pass, which played so important a part in the rebellion. For this and the other engravings we are indebted to Illustrirte Zeitung.

We have also a reproduction from a photograph of some Khyber rifles. These troops the English authorities thought it best to disarm, although no open signs of disloyalty were given. These and other details are, however, well known to our readers through the newspapers, and we do not purpose to dwell upon them at length. Small as may seem the immediate significance of these troubles, they bear upon relations of supreme importance to at least two of the great European powers. We are referring to the position in which Russia and England find themselves to day in Asia. At the end of the last century Anglo-Russian affairs in Asia had a very different aspect from the present state of things. There extended then between them the whole of China on one side, and Turkestan, Persia and Afghanistan on the other. But the year 1796 brought the first of those changes which gradually brought the Russian frontier within a comparatively short distance from English territory. This first step forward by the Russians was invited by request on the part of the King of Georgia for help against the Persians. Catherine the Second, then on the throne, granted the aid, and went further, taking Derbent near the Caspian Sea, Daghestan, and nearly all the land to the river Kur. Georgia was formally placed under Russian protectorate soon after, to be annexed to the great empire. In the early years of the nineteenth century the first step was followed up by the taking from the Turks of the mouth of the river Phasis, and a little later by the annexation of the Persian province of Shirvan, and of Armenia from beyond the Kur to the Aras and Mount Ararat. Thus the barrier of the Caucasian Mountains

was passed by. Besides, these conquests gave the Russians a most advantageous position from which to conduct operations against Turkey in Asia and Persia, and to guard the Caspian Sea and the Black Sea. For years the inhabitants of the mountainous districts held their liberty. But, in the year 1859, Shamyl, the Caucasian hero, after having ruined ten Russian armies, was taken prisoner, and with him fell the cause he had fought for. Thus Russia possessed, south of the Caucasus, eight large provinces, backed on one side by the mountains held by her troops, and protected on the flanks by two seas and strong fortresses. Thus a strong advanced post of the Russian empire was formed, whose center was at Tiflis.

In the meantime the English on their side were also advancing in the opposite direction. In 1816 they compelled the mountain kingdom of Nepaul to acknowledge their supremacy, and two years after Dekhan was reduced to the same dependence. Each of these states received at its royal court an English officer, who watched the king's movements, and at the capital was stationed a British garrison to insure obedience. The pay of this garrison was derived from the taxes levied in certain portions of the king's realm. Thus the English could keep a numerous army without going to any expense.

In 1824 to 1826 two hundred miles of coast in Burma were acquired, the state of Assam became tributary to Great Britain, as did Singapore and Malacca. This made the Gulf of Bengal a British sea, and placed the great commercial road to India and China in the hands of the great colonizing nation.

The next move on the part of Russia was almost directly aimed at the English. The Czar prevailed on his vassal, the King of Persia, to make an attack on Herat, one of the two great cities on the frontier of India and Persia. The first attempt was made in 1833, but without success. Again the Shah sent his troops to Herat four years later, but with the same result. In the next year a third expedition was made, for which the Czar supplied the Persian army with officers, to conduct the siege. England was jealously watching these movements. When the Persian army arrived at their destination, they found the fortress occupied by an English garrison. Forces were also posted in the immediate neighborhood. Against such odds the Shah dared not to continue in his original plans, and he had to retreat. This was in 1838. The event represented a severe check to the Russians. They tried in the following year to make up for the defeat by an attack on Khiva, a town on the second great Indian road. But the army had to cross vast deserts, and nearly all perished on the way.

So far, the English had an indirect advantage. But in 1842 came the Afghan war. Fifteen thousand Englishmen were massacred in the enemy's territory. A new army was sent to avenge the defeat, but it became clear that it was unsafe for the English to venture too far from their peninsula. Since that time it has been their general policy to assume a defensive position, making Herat their outpost, while the Russians have steadily advanced, taking all the most important towns of Turkestan, even Samarkand, one of the ancient Asiatic capitals, and Goukdja, the chief city of Jungarh, which holds some important mountain passes. Thus the two powers, Russia and England, are brought very near each other, and naturally any check received by one is an advantage to the other. It is in this sense that the Indian frontier risings assume a rather important aspect. The Standard speaking of these matters says: "The inner condition of India is not so favorable as that we may with confidence look forward to a costly war at the frontiers."

Just the district where the recent troubles occurred lies at the very point where Russian and English interests meet. Not a hundred miles away the land is the Czar's. These circumstances make the late outbreaks in the far East a link in a chain of events which seems to be gradually moving toward a climax which may prove a point of great issue in the world's history.

To cut glass take a piece of thin, strong thread, soak it with kerosene, methylated spirits or turpentine; then lay it firmly round the portion where the cut is to be made, light the thread and turn the glass so that the flame is below. On pouring water over the glass you will obtain a clean cut where the thread was laid.—Uhland's Wochenschrift.

A TWO WEEKS' TRIP WITH ESKIMO DOGS.*

By the Rt. Rev. JERVOIS A. NEWNHAM, Bishop of Moosonee, B. N. A.

ONE does not generally expect hardship on a seaside trip, yet I expected some. I was to go some fifteen miles down a great river to the bay, then two or three days along the bay, and then ten miles up another big river, and to return the next week the same way. This I have done, traveling for two days each way over the salt water, and yet neither seeing nor smelling it, and traveling over the water by a train! I traveled by train, yet not on wheels, a train which made its own track and did not use fuel or water, and only went at the rate of four or five miles an hour, and only from about 5 A. M. to 2 or 3 P. M. each day. The rest of the time we spent in camp. For those three days and nights we were in the open air, and at what a temperature! Always far below zero, 45 or 50 degrees of frost by day and as much as 60 or 62 at night! A strange seaside trip, surely! But before telling my story, let me explain the above riddle by saying that the "train" was a dog train, composed of a sled drawn by eleven Eskimo dogs, and driven by an "Injun," not an Injuneer—I mean an engineer; and that we traveled over the ice, three feet thick, with two feet of snow on top, which entirely hid the salt water, so that we could only travel by daylight, and had to stop at certain fixed places, where we could find wood for the campfires, and that we slept on the ground, or rather snow, in our cotton tent, or in the wigwams or tents of poles and bark, erected at the regular stopping places.

My home is at Moose Fort, and I wished to visit our mission at Rupert House, confer with the missionary there and see the residents. On the twenty-sixth of February the dogs from Rupert House arrived here and brought me an invitation to return with them,

* From the Independent.

BRITISH ARMY—NATIVE ARTILLERYMEN.

KHYBER RIFLES.

which I gladly accepted, and made my preparations. These consisted in getting suitable food cooked for three or four days, gathering a bundle of blankets and rabbit skin rugs to wrap round me in the sled and sleep on at night, packing a small box with clothes, etc., for use at Rupert House, and looking out my deerskin coat and snowshoes. The food needs to be very simply and ready cooked; for we do not stop during the day to cook, and at night we have to thaw our food, and again in the morning. I took a loaf and some scones, the latter mostly to carry in my pocket and eat at midday; some partridges ready cooked, a little cooked beef and bacon, and a packet of soup powder; also tea and sugar, salt and butter, some frozen cream, frying pan, kettle, cup, plate, etc. Monday, the twenty-second of March, I was up soon after four o'clock, only to find a snowstorm raging, so that I could be down to await developments. At seven o'clock the storm was so heavy that we abandoned the idea of starting that day. The snow fell all day, the worst storm of the season. So we knew we were in for a hard trip.

Tuesday I was up at 3:30, and after a hasty breakfast, donned my "Husky" coat of deerskin with the hair on and started for the dogs. It was a fine morning, but promised to be very cold all day, and the wind right in our teeth. Well, here we are down on the ice, and the dogs all harnessed and impatient to start. Let me describe. The sled consisted of a narrow box four feet long, the front half being covered or

FORT ALI-MUSJID, KHYBER PASS.

boxed in, mounted on a floor eight feet long resting on runners. In this box the passenger sits wrapped in rabbit skin so that he can hardly move, his head and shoulders only projecting. In front and behind and on top of the box is placed all the luggage, covered with canvas and securely lashed to withstand all the jolting and possible upsets, and our snowshoes within easy reach. An important item is the dog whip, terrible to the dogs if used by a skillful hand and terrible to the user if he be a novice; for he is sure to half strangle himself or to hurt his own face with the business end of the lash. The whip I measured had a handle nine inches long and lash thirty feet, and weighed four pounds. The lash was of folded and plaited seal hide, and for five feet from the handle measured five inches round, then for fourteen feet it gradually tapered off, ending in a single thong half an inch thick and eleven feet long. Wonderful is the dexterity with which a driver can pick out a dog, and almost a spot on a dog, with this lash. The lash must be trailing at full length behind, when a jerk and turn of the wrist causes it to fly forward, the thick part first and the tapering end continuing the motion till it is at full length in front, and the lash making the fur fly from the victim. But often it is made to crack like a pistol over the heads of the dogs as a warning. The eleven dogs were harnessed to the front of the sled, each by a separate thong of seal hide, all of different lengths, fastened to a light canvas harness. The nearest dog was about fifteen feet from the sled and the leader with bells on her about fifty feet, the thongs thus increasing in length by about three feet. When the going is good the dogs spread out like the fingers of a hand, but when the snow is deep they fall into each other's tracks in almost single file. As they continually cross and recross each other, the thongs get gradually plaited almost up to the rearmost dog, when a halt is called, the dogs are made to lie down, and the driver carefully disentangles them, taking care that no dog gets away meanwhile. They are guided by the voice, using "Husky," i. e. Eskimo words: "Owk!" go to the right, "Arrah!" to the left, and "Hoit!" straight on. But often one of the men must run ahead on snowshoes for the dogs to follow him. See me now in my box, carefully wrapped up, all but my face, in blanket of plaited rabbit skins, a jerk is given to the sled to loosen it, "Hoit!" and we are off! I have often seen the dogs start at a gallop of six miles an hour; but the snow is deep and we go at a slow trot, the men running and helping the dogs. It is slow and cold for me, but gradually Moose Fort is left behind as we go down the river.

At eleven o'clock we halt ten minutes for refreshments. We are in no anxiety lest the train will start before our coffee has cooled enough for us to drink it; our hurry is lest it and the sandwich should freeze before we consume them. An al fresco lunch sounds very charming, but there are decided drawbacks. Standing or sitting with fifty degrees of frost, the mustache and beard heavily laden with icicles, so that it is difficult to open the mouth without bringing tears to the eyes, by reason of the hairs pulled out, the fingers freezing if they are kept out of the mittens for a few minutes for eating purposes, the bread frozen, or beginning to freeze the moment it is taken from the pocket—these are not the best constituents for a picnic. We never stop to cook in the middle of the day's journey; but a jar of boiling tea has been stowed in the blankets, and has not lost all its warmth, and a sandwich or a scone carried in an inner pocket will not be frozen very hard. On again, and at 1 P. M. we are passing Natatishe Point, twenty-two miles from Moose. We reach the next point, Big Stone, before three o'clock; but as it was twenty-five miles to the next possible stopping place, we had to be content to go no further that day. We had a cotton tent with us, and a small portable stove, and the first thing was to erect these in the shelter of the bush, and to get some wood for the fire. This took some time, and I found the waiting miserably cold work, chilling me to the bone. Of course the floor of our tent, which is also our bed, is the trampled surface of snow, with a few pine branches laid on top. When the fire in the stove was burning my bedding was laid in the tent, and, sitting on this, I proceeded to unpack and thaw my food and to thaw myself. The stove had not been very well put up, and kept up a constant leakage of most pungent smoke, which soon caused me real agony in the eyes. My supper of bread and butter and a bird, ready cooked, needed only to be thawed, and water to be boiled for tea, but the thawing takes long, and it was half past four before it was ready. I also found that partridge shot in December, frozen till March, then cooked and frozen again, thawed and so eaten, is rather dry and uninteresting food. The men were busy cutting dry firewood, attending to the dogs and cooking their supper till later than this. The dogs are unharnessed and chained to trees, out of reach of each other, as they are very quarrelsome, and presently fed with frozen fish, rabbits, or seal blubber, as the case may be. They sleep in the snow, coiled up without any shelter, and get very little attention. A tent with a stove is more comfortable for us than the open wigwam fire in the middle, which is always very bad for smoke. The cotton tent gets almost too hot while the stove is in full draught; but everything in it, except the sleepers, freezes solid at night. It was too smoky for comfort, so as we had to get up very early, we lay down at eight o'clock. My bedstead was snow, mattress pine branches, bed of rabbit skin and blanket of ditto. I have learned to sleep like an Indian, with head under the blanket; but even so, one gets very cold before midnight, and that and the hard bed made my rest very much broken. I think that the men must have lit the fire very early next morning. About three o'clock I awoke (indeed, I awoke several times before that, owing to the hardness of the bed and the cold), and put all my breakfast materials to thaw; but did not get up finally till four o'clock. It took us till six to thaw or cook our breakfast and eat it, so that we did not start till 6:30.

The day was fine for us, but the snow was deep and soft, making heavy traveling. It was also cut into a succession of ridges by the winds; so that it was like crossing a plowed field diagonally. It was hard on the dogs, hard on the passenger, if he rode, owing to the constant bumping of the sleigh, and very awkward snowshoeing over the ridges. The drivers had to walk the whole way, and I walked for an hour. I had come with borrowed snowshoes, which were too short and tight at the toes, so that I was sore and lame after half an hour. However, I managed two hours' more tramp after lunch, at 10:30, and we reached East Point at noon. It was too late to go on to the next camp (twenty miles at least), so we made for the tent here and were in it by 2 P.M.; very early to stop, but there was no help for it. Here we used the "tent," i. e., not our cotton markee, but a fixture of logs and poles and boughs, about fourteen feet in diameter, and open at the top, through which opening the smoke is supposed to go. One was roasting on the side near the fire, and freezing on the further side. The smoke was dreadful, and very painful to my eyes; I could hardly read prayers for the pain and tears, and was glad to turn into bed at eight o'clock. It was a very cold night (about 65 degrees of frost, or 33 below zero), but I slept fairly well, only felt a little rheumatic and sore from the hard, cold ground. Awaking in the night, I found the hair on my forehead stiff with ice from my breath, and pillow and blankets ditto. Thursday, up at four o'clock and off at 6:15. A bitter morning, and I found the cold while preparing to start almost unbearable; but I got right under my sleigh-robes and dozed. We had to cross two or three small bays, about twenty miles to Cabbage Willows. When half way across an Indian came out to meet us. He reported "no rabbits, and family starving," i. e., very hungry; so we gave him some food from our small store. We found out afterward that he makes a regular business of stopping people passing with the same story, they being a lazy, shiftless lot. Reaching Cabbage Willows at 1 P. M., we determined to press on. Then came the hardest bit of all. Here the snow had drifted to a great depth; all had to walk, one man tramping a path for the dogs, which fell into single file, the leader being almost hidden in the snow. The second man and I walked by the sled, holding it up, and often helping to push it when the dogs stuck fast.

We reached Black Bear Point at six o'clock and hastened to get tent fixed, wood cut, etc., before dark. We used our cotton tent and the stove here; the wood was rather green, and it took a long time to get the stove to burn and the food to thaw. The night and next morning were passed as before, only that we got up about 3 A. M., and made an early start. It still kept cold with a strong wind in our faces, so that, but for a short walk, I kept down under the blankets. About 9 A. M. we stopped to disentangle the dogs for the last time, and the leader was stripped of her harness and robed in a set gay with ribbons and colored wools, in which to arrive at the place. Directly after this we rounded a point and saw Rupert House a few miles off and knew that they would at once see us. But it was a tedious two hours before we arrived. Rupert House is prettily situated on a high bank of the river, much higher than anything we have round flat Moose Fort. I forgot to say that all the morning and part of the day before we had in sight, far to the north, Sherrick's Mount, a really high hill, and the only hill to be seen for many days' journey round Moose. A gang of men and boys came down the bank and gave the dogs a help up it, so that we arrived in style, on the run, with a great team, human and canine, to receive a most hearty greeting from Mr. M., in charge of the post. On a journey like this toilet exercises are of the most meager kind, and undressing is not practicable; so the first thing to do was to get out of my deerskin coat, which was always shedding its hairs over everything, including my food, and then to have a good wash and thorough change. I cannot now tell of my pleasant stay at Rupert House, visiting everybody, whites and Indians, holding services in the church, and enjoying the rest and the visit generally, but must pass on to my return, which I must dismiss with a few lines. The weather was fine while I was at Rupert House, and a high wind blowing all the time, so we expected the snow to be well packed and make the return journey easier. I had the Rev. E. R., native missionary, and his man with me this time as my crew, and they were naturally not as expert at camping arrangements as the men I had before. Also instead of eleven good dogs I had only eight second-rate; so I did not expect to make such good time. The route was the same as that by which we came, but the division of it different. We started at 7 A. M., and managed to reach Cabbage Willows before dusk. Here is a fixed tent which we used instead of our cotton one. It was a mistake, for it needed more wood, which we had to cut, was very cold, and was

the worst for smoke so far. However, we managed somehow. My present crew were early risers, or we should not have reached home as soon as we did. They had the fire going by two o'clock, and I was up by three; but they were so slow over their preparations that it was after six when we started. I was up each morning by three at the latest, but we only once got off before six; yet I was afraid to lie on, lest they should do the same, and we should be later still.

The second day we only reached East Point; the third, by starting earlier and traveling later, we passed Bigstone without stopping and camped at Natatishe Point. Somehow on the second day I sprained the sinews of my right hand, which swelled very much and became very painful and continued so all the journey. At Natatishe we used our markee and camped very luxuriously on top of a hard snowdrift four feet deep. The fourth day we started early and hoped to reach Moose before noon. But traveling was hard and dogs tired, and we had a tedious time. I tramped a good bit of the way. So we struggled along, getting our dogs into a run here and there, where the snow was not deep, past Pilgrims, the tail of our island, the servants' houses, the factory, along the ox-track, and then a scramble up the bank and through the gap in the fence into our field at the side of the house and so at home just as the Indian children were going into afternoon school at two o'clock. Thus ended my first dog trip. Some fun, some discomfort at least, toes frostbitten, nose and cheeks peeled from the sun and frost, well tanned, and with a fresh stock of health and appetite.

THE GROTTO OF LA BALME.

ALTHOUGH it is annually visited by about 4,000 tourists, most of whom come from Lyons, the Grotto of La Balme, of which we reproduce herewith a few photographic views sent us by M. Boissonnas, the well known artist photographer, does not as yet possess all the reputation that it merits. It is situated in the department of the Isère, at about four miles from the station of Lagnieu and in the immediate vicinity of the pretty little village of La Balme, where one easily finds for hire the change of clothing, lamps and guides that are

FIG. 2.—BACK OF THE LAKE GALLERY.

necessary for visiting it without danger. The grotto, which is hollowed out in a low Jurassic chain, is spacious, easy of access and remarkably dry in all its galleries, save at the epochs in which its lake overflows as a consequence of prolonged rains. It was, of old, a place to which religious pilgrimages were made, and at present contains enough natural curiosities to attract even those whose æsthetic or scientific sense is alone developed. We shall speak of it from this view point solely.

The entrance of the grotto is immense, "one of the grandest known," as M. Martel asserts in his book entitled "Les Abîmes." It is 100 ft. in height and 68 in width. Unfortunately, its aspect is marred by a chapel dedicated to the Virgin, the stairway of which intersects this vast opening transversely and diminishes the artistic effect of it. Back of the chapel, the vault of the grotto is about 50 ft. higher still, so that the visitor finds himself in an immense chamber (the grand nave), decorated with calcareous concretions, whence he can enter the three main passageways, each of which presents an ensemble of peculiar characters. The one to the left, which is quite narrow at its origin, leads to Mandrin's Labyrinth, so called because the notorious brigand of that name took refuge therein at various times and even established there, it is said, a workshop for the manufacture of counterfeit money.

Several tortuous galleries, connected with each other and intersected by cavities in the form of chambers, justify the name of labyrinth given it in the vicinity.

The central gallery, which is wider than the preceding, and is no less uneven, affords a passage for the water which proceeds from an overflow of the lake, and which flows in a torrent over the irregular bottom, in which are hollowed out huge pot holes, multiform basins and fissures wherein the water accumulates, and along the edge of which it is prudent to walk slowly in order to avoid disagreeable duckings.

Quite near the entrance are situated the Grotto of Diamonds, in which hundreds of stalactites sparkle in the light of Bengal fires, and the Basin Amphitheater, wherein there is a succession of superposed bowls which empty their contents one into another and, at the time of high water, form superb cascades. The lake, which occupies the back of this gallery, results from the union of the waters that have infiltered from the summit of the mountain and perhaps also from other and unknown sources.

Bourrit, its first explorer, in the last century, unhesitatingly plunged into it, and, pushing before him as he swam a float upon which candles were fixed, prolonged his excursion to a point at which the low ceiling presented a barrier to his further progress. Such prowess, which has become legendary, would be perfectly superfluous to-day, since a small boat permits the traveler to traverse the lake from one end to the other, and to admire the limpidity of its water and the curious conformation of the ceiling that surmounts it. Such a trip is impressive and cannot be too highly recommended.

As for the passageway to the right, that rises quite rapidly through rocks that have fallen as far as to the Monk's Chamber, one of the most spacious of the entire grotto. This chamber is a wonder. It is strewed with concretions of the most diverse shapes, and upon its floor there rests a huge stalagmite, 10 ft. in height, the

FIG. 1.—THE MONK'S CHAMBER IN THE GALLERY OF BATS.

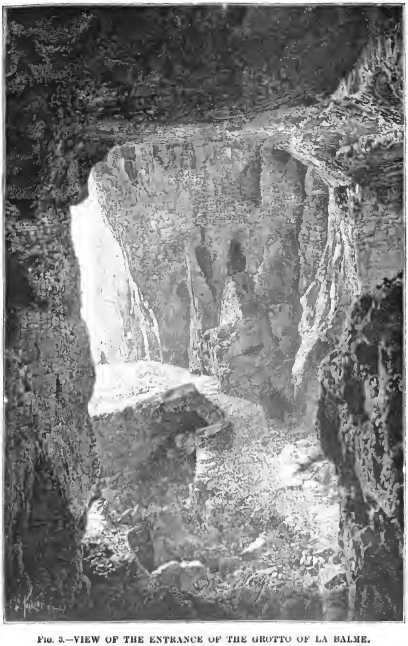

FIG. 3.—VIEW OF THE ENTRANCE OF THE GROTTO OF LA BALME.

form of which somewhat recalls that of a monk, and which is surrounded by other and similar mamelons that have been continuously enlarged by the falling of water, drop by drop, from the vault. From the reproductions of the photographs that we give may be seen the effect produced in this chamber by the play of the light from a powerful magnesium lamp, the rays of which penetrate to the most distant corners. At a few yards further along is found the great fountain, which is formed of an assemblage of basins in which water is in constant circulation and in the center of which stands a magnificent column formed of the union of a stalactite with a stalagmite measuring nearly 5 ft. in diameter.

In retracing our steps in order to reach the great nave, the starting point of these main galleries, we may visit a strange collection of tortuous excavations communicating with each other by narrow fissures. This is the labyrinth of Francis I, in the center of which there is a sort of natural saloon in which the king had a breakfast served at the time of his visit to the grotto.

We have no intention of describing in detail this remarkable cavern, which ought to be known to all speleologists, and to which M. Martel devotes a simple note in his classical work. The concretions that project from its walls have, in places, forms that recall certain organic structures (a beehive, a recumbent lion, a weeping willow, a toadstool, a swallow's nest, etc.), and the conformation of the pot holes, basins and ladders furnishes valuable indications as to the manner in which the grotto was fashioned. Let us be content to add that it requires at least three hours to explore it, and that M. E. Chantre, the learned archeologist of Lyons, has found therein vestiges of human industry, although at the present time it is inhabited only by bats and spiders.—La Nature.

HIBISCUS MANIHOT—FLOWERS SULPHUR-YELLOW, DEEP PURPLE EYE.

HIBISCUS MANIHOT.

EITHER this is a very variable plant, or several species are confused with it. The plant shown by Mr. Fulford, gardener, Moor Hall, Cookham, at Drill Hall, on September 7, 1897, and certificated by the Royal Horticultural Society, differed widely from the plant grown in the temperate house at Kew under this name. Nor is the Kew plant annual, the example under notice being about ten years old. It is cut down early in spring, and by the autumn it makes shoots 6 feet or so high, as thick as a man's finger, and it develops terminal and axillary racemes of flowers in September, being finely in flower now. The largest leaves have petioles 18 inches long, a pedately-lobed blade 18 inches across, the lobes irregularly notched or toothed. Both petiole and blade are [thinly] clothed with soft, very fine hairs. In habit and leaves the plant resembles a vigorous castor oil plant, save that it is of a uniformly dark green color. The flowers are fully 6 inches across, their color being clear sulphur yellow, with a maroon eye-like blotch at the base. The peduncle is 2½ inches long; the calyx lobes, of which there are four, are over an inch long, by three-quarters of an inch broad at the base. The flowers last only a day or so, but they are borne in large numbers and in quick succession. For a large greenhouse this plant is worth attention. It is ornamental even when not in flower. It thrives better when planted in a border than when grown in a pot. —W. W.

[We believe that this is a very variable plant, and it is possible that some might consider more than one species included under the same name. That is not our view, nor has the inspection of the plant growing in the temperate house shaken our conclusion. The species seems distributed throughout the tropics of the Old World, but whence it originated is not clear. It is said to have been introduced from China, but the species is not enumerated in Forbes' and Hemsley's enumeration of Chinese plants. In the monograph of Malvaceæ, contributed to the Flora of British India by the present writer, it is not recognized as a wild Indian plant (see vol. i, 1875, p. 341). It is not mentioned in Roxburg's Flora Indica, nor in the Flora of Tropical Africa, nor in Mr. Baker's Flora of Mauritius, nor in Grisebach's Flora of the West Indies. On the contrary, it is included as a native plant in Franchet and Savatier's Enum. Plant. Japon. (1875), i, p. 64, and in the Flora of Queensland (Bentham Flora Aust., i, 209). Linnæus, of course, could not have known of this locality. Probably a search through some of the pre-Linnæan books might afford some information, and also give the explanation of the name Manihot, also applied to a Euphorbiaceous genus. Evidently there are some interesting historical details to be unearthed when time and opportunity permit. In the meantime, we can all admire the loveliness of the flower, and although it is of no use for cutting, few things confer greater beauty on the warm greenhouse. We hope Mr. Watson will contrive to fertilize the flower, and secure perfect seed for botanical, as well as for cultural, purposes. It has been cultivated in this country, according to The Botanical Magazine, since 1712, at which period it was sent to the Royal Society as one of the fifty specimens then required to be delivered annually to that Society by the Society of Apothecaries.—ED.]—The Gardeners' Chronicle.

THE CAPRICES OF ORCHIDS.

THE family of plants known as orchids present many anomalies puzzling to botanists. Most of them cannot seed unless some insect or bird assists in effecting fertilization. As a consequence of having the work done through agents, it generally goes undone. Of every thousand of orchid flowers, a very small portion ever perfect seed. But even this seems to have been anticipated, for when a seed vessel does mature, the seeds are as the sands of the sea shore in number, and they are as small and as light as dust; though only one capsule in a large forest should mature, the whole forest area would be stocked full of plants did the seeds grow. But here again comes in a sort of contradiction, for the seeds seem to grow but rarely.

In our own country it has been noted that one of the slipperworts (Cypripedium acaule) usually produces a few seed vessels that mature early. Yet only about the same number of plants are found from year to year as were originally observed in the location. The seeds are widely distributed, but do not grow. The skillful horticulturist, however, makes the seed grow very easily at his bidding.

With a little practice he can get every one to grow as easily as beans. They require, he finds, a very nice combination of conditions to germinate—conditions that are rarely found in a state of nature. The curious question arises, Why should Nature make such complex arrangements with such small results? But here again there seems to be a foreknowledge that these intricate arrangements may fail, and a provision is made for defense by giving them a high power of endurance. None of them are annuals, and they are so constructed that neither an excess of heat nor moisture endangers their existence. They will stay for months dormant under long continued heat and drouth, and push forth at once in all the glory of their showy flowers and luxuriant leaves as soon as a few warm showers come. But the inconsistency of their characters is one of their most striking marvels.

In some parts of the world, especially in Australia, a plant that has long borne flowers of a certain genus and species will, of a sudden, exhibit flowers and foliage of what had hitherto been regarded by botanists as of a totally different genus, and it seems like a stroke of the magic art to have these many different structures proceed from the same individual. In the same line, the hybridist enters the field with his orchid wonders. He finds that what science has told him are distinct genera will cross fertilize, and the product be a race of orchids for which distinct generic names have to be coined. What is more remarkable is that these hybrids, from these distinct genera, are as abundantly fertile as their parents, and the hybrid characters are produced and reproduced by the progeny of the hybrid parent just as perfectly as a normal species fertilized by its own pollen. In fact, no orchid grower despairs of producing hybrids between any species or genera. He will tell us that success or non-success is merely a matter of experiment. Continually the most surprising combinations are announced. One of the most recent successes is between two genera comparatively common in our greenhouses and conservatories. One is the purple butterfly orchid (Zygopetalum Mackayi), the other the tooth-tongued orchid (Odontoglossum crispum). The contrary behavior of orchids in these various stages of life is proving a great strain on botanical science. It seems impossible to arrange them into genera and species under any system that will prove of stability. The fecundation of orchids by artificial means is so easy that many amateur growers are finding in it a new source of floral gratification. The little beak-like cap at the apex of the column of stamens and pistils is pushed off, and the pollen masses exposed. These are placed on the stigma, and the work is done. The interest is in the form of the capsules that follow. In the case above cited, the purple butterfly orchid, a pear-like seed vessel, as large as the upper segment of a large thumb, follows, and not only this, but the petals of the orchid get a renewed lease of life by the operation. Instead of falling a few days after expansion, they erect themselves, and give some interest for a month or more.—Independent.

THE BEGINNINGS OF AMERICAN ASTRONOMY.*

IT is impossible, even in the briefest sketch, not to emphasize the debt of American science and learning to the intelligent interest and patronage of our early presidents—Washington, John Adams, Jefferson, Madison, Monroe, John Quincy Adams. The powerful impetus given by them and through them has shaped the liberal policy of our governments, national and State, toward education and toward science. Sir Lyon Playfair, in his address to the British Association for the Advancement of Science (1885), has recognized this influence in the truest and most graceful way. He said: "In the United Kingdom we are just beginning to understand the wisdom of Washington's farewell address to his countrymen (1796) when he said: 'Promote, as an object of primary importance, institutions for the increase and diffusion of knowledge; in proportion as the structure of a government gives force to public opinion, it is essential that public opinion should be enlightened.'"

Until the Revolution (1776) American science was but English science transplanted, and it looked to the Royal Society of London as its censor and patron. Winthrop, Franklin and Rittenhouse were, more or less, English astronomers. Franklin was the sturdiest American of the three. As early as 1743 he suggested the formation of the American Philosophical Society, of Philadelphia. John Adams founded the American Academy of Arts and Sciences in Boston in 1780. These two societies, together with Harvard College (founded in 1636), Yale College (1701), the University of Virginia (founded by Jefferson in 1825) and the United States Military Academy at West Point (1801), were the chief foci from which the light of learning spread. Other colleges were formed or forming all over the Eastern and Middle States during the early years of the century.

The leading school of pure science was the Military Academy at West Point, and it continued to hold this place until the civil war of 1861. From its corps of professors and students it gave two chiefs to the United States Coast Survey; and the army, particularly the corps of engineers, provided many observers to that scientific establishment, besides furnishing a large number of professors and teachers of science to the colleges of the country. The observatory of the academy was founded by Bartlett, in 1841, and much work was done there, only a small part of which is published. The Coast Survey was a school of practice for army officers, and their experience was utilized in numerous boundary surveys during the period 1830-50. Col. J. D. Graham, for example, was astronomer of the survey of the boundary between Texas and the United States in 1839-40; commissioner of the northeast boundary survey, 1840-43; astronomer of the northwest boundary survey, 1843-47; of the boundary between the United States and Canada, 1848-50; of the survey of the boundary between Pennsylvania and Virginia, 1849-50; of the boundary survey between Mexico and the United States, 1850-51. The names of Bonneville, Talcott, Cram, Emory and other army officers are familiar in this connection, and their work was generally of a high order. It was in such service that Talcott invented or reinvented the zenith telescope, now universally employed for all delicate determinations of latitude. The mechanical tact of Americans has served astronomy well. The sextant was invented by Thomas Godfray, of Philadelphia, in 1730, a year before Hadley brought forward his proposal for such an instrument.† The chronograph of the Bonds, the zenith

* From Science.

† In 1700 Sir Isaac Newton sent drawings and descriptions of a reflecting sextant to Halley for his advice. At Halley's death these were found among his papers. Hadley's device (1731) was undoubtedly derived from Newton's MSS. The Royal Society, of London, granted £200 to Godfray for his invention, which his brother, Capt. Godfray, had previously put into practical use in the West Indies.

telescope of Talcott and the break circuit chronometer of Winlock are universally used to-day. The diffraction gratings of Rutherfurd were the best to be had in the world till they were replaced by those of Rowland. The use of a telescope as a collimator was first proposed by Rittenhouse. The pioneer opticians of the United States were Holcomb (1826), Fitz (1846 or earlier), Clark (1845), Spencer (1851). Only the Clarks have a world-wide reputation. Würdemann, instrument maker to the United States Coast Survey (1834), had a decided influence on observers and instrument makers throughout the United States, as he introduced extreme German methods and models among us, where extreme English methods had previously prevailed. The system of rectangular land surveys which proved to be so convenient for the public lands east of the Rocky Mountains was devised and executed by Mansfield, a graduate of the Military Academy.

The list of army officers who became distinguished in civil life as professors in the colleges of the country is a very long one. Courtenay (class of 1821 at West Point) was professor of mathematics at the University of Pennsylvania, 1834-36, at the University of Virginia, 1842-53, and was the author of admirable text books. Norton (class of 1831) became professor at New Haven, and wrote a very useful text book of astronomy in 1839; and the list could be much extended. The excellent training in mathematics at West Point (chiefly in French methods) early made itself felt throughout the whole country. The mathematical text books of Peirce, of Harvard, and of Chauvenet, of the Naval Academy, brought the latest learning of Europe to American students. Mitchell (class of 1829 at West Point) was the only graduate who became a professional astronomer (1842-61). His direct service to practical observing astronomy is small, but his lectures (1842-48), the conduct of the Cincinnati observatory (1845-59), and his publication of the Sidereal Messenger (1846-48), together with his popular books, excited an intense and widespread public interest in the science, and indirectly led to the foundation of many observatories. He was early concerned in the matter of using the electric current for longitude determinations, and his apparatus was only displaced because of the superior excellence of the chronograph devised by the Bonds. His work was done under immense disadvantages, in a new community (Ohio), but the endowment of astronomical research in America owes a large debt to his energy and efforts.

The Navy and the United States Naval Academy (founded by Bancroft in 1845, at the suggestion of Chauvenet) were very active in astronomical work. Chauvenet (Yale College, 1840) published a text book of trigonometry, in 1850, which had an important share in directing attention to right, elegant and general methods of research. His astronomy (1863) is a handbook for all students. Walker, Gilliss, Coffin, Hubbard, Ferguson, Keith, Yarnall, Winlock, Maury, Wilkes, were all connected with the navy, more or less intimately. Walker's career was especially brilliant; he graduated at Harvard College in 1825, and established the observatory of the Philadelphia High School in 1840. He was the leading spirit in the United States Naval Observatory at Washington (1845-47) and introduced modern methods into its practice at the beginning. From the observatory he went to the coast survey to take charge of its longitude operations, and he continued to direct and expand this department until his death, in 1853. To him, more than to any single person, is due the idea of the telegraphic method ("the American method") of determining differences of longitude. His assistant in this work was Gould, who succeeded to the charge of it in 1853. His researches extended to the field of mathematical astronomy also, and his theory of the planet Neptune (then newly discovered) marks an important step forward. His investigations and those of Peirce were conducted in concert and attracted general and deserved attention.

The exploring expedition of Wilkes required corresponding observations to be made in America, and during the period 1838-42 William Bond, at Dorchester, and Lieutenant Gilliss, at Washington, maintained such a series with infinite assiduity and with success. The results of Gilliss' astronomical expedition to the southern hemisphere (Chile, 1849-52) were most creditable to him and to the navy, though his immediate object—the determination of the solar parallax—was not attained.

The Coast Survey began its work in 1817 under Hassler, a professor from West Point, who impressed upon the establishment a thoroughly scientific direction. Bache, his successor (a grandson of Benjamin Franklin), was a graduate of West Point in the class of 1825, and took charge of the survey in 1843. He is the true father of the institution, and gave it the practical efficiency and high standard which characterized its work. He called around him the flower of the army and navy, and was ably seconded by the permanent corps of civilian assistants—Walker, Saxton, Gould, Dean, Blunt, Pourtales, Boutelle, Hilgard, Schott, Goodfellow, Cutts, Davidson and others.

Silliman's (& Dana's) American Journal of Science had been founded at New Haven in 1818, and served as a medium of communication among scientific men. A great step forward was made in the establishment of the Astronomical Journal by Dr. Gould on his return from Europe at the close of 1849.* Silliman's Journal was chiefly concerned with the non-mathematical sciences; though it has always contained valuable papers on mathematics, astronomy and physics, especially from the observers of Yale College—Olmsted, Herrick, Bradley, Norton, Newton, Lyman and others. In Mason, who died in 1840 at the age of 21, the country lost a practical astronomer of the highest promise.† Gould's Journal was an organ devoted to a special science. It not only gave a convenient means of prompt publication, but it immediately quickened research and helped to enforce standards already established and to form new ones. The Astronomical Notices of Bruennow (1858-62) might have been an exceedingly useful journal with an editor who was willing to give more attention to details, but, in spite of Bruennow's charming personality and great ability, it had comparatively little influence on the progress of the science.

* The Astronomische Nachrichten had been founded in Altona, by Schumacher, in 1821.

† See International Review, vol. x. p. 565.

The translation of the Mécanique Céleste of Laplace by Nathaniel Bowditch, the supercargo of a Boston ship (1815-17), marks the beginning of an independent mathematical school in America. The first volume of the translation appeared in 1829; at that time there were not more than two or three persons in the country who could read it critically. The works of the great mathematicians and astronomers of France and Germany — Laplace, Lagrange, Legendre, Olbers, Gauss, W. Struve, Bessel—were almost entirely unknown.

Bowditch's translation of the Mécanique Céleste, and, still more, his extended commentary, brought this monumental work to the attention of students and within their grasp. His Practical Navigator* contained the latest and best methods for determining the position of a ship at sea, expressed in simple rules. American navigators had no superiors in the first half of the century. Nantucket whalers covered the Pacific, Salem ships swarmed in the Indies, and the clipper ships made passages round the Horn to San Francisco which are a wonder to-day. Part of their success is due to the bold enterprise of their captains (who were said to carry deckloads of studding sail booms to replace those carried away!) but an important part depended on their skill as observers with the sextant. One of the sister ships to the one of which Bowditch was supercargo was visited at Genoa by a European astronomer of note (Baron de Zach), who found that the latest methods of working lunar distances to determine the longitude were known to all on board, sailors as well as officers. His bewilderment reached its climax when the navigator called the negro cook from the galley and bade him expound the methods of determining the longitude to the distinguished visitor.

On Bowditch's own ship there was "a crew of twelve men, everyone of whom could take and work a lunar observation as well, for all practical purposes, as Sir Isaac Newton himself." Such crews were only to be found on American ships in the palmy days of democracy. All were cousins or neighbors, and each had a "venture" in the voyage. But these anecdotes may serve as illustrations of the intellectual awakening which came about as soon as our young country was relieved from the pressure of the two wars of 1776 and 1812. An early visitor, Baron Hyde de Neuville (1805), felt "an unknown something in the air," "a new wind blowing." This new spirit, born of freedom, entered first into practical life, as was but natural; science next felt its impulse, and, last of all, literature was born. Emerson hailed it (in 1837) "as the sign of an indestructible instinct." "Perhaps the time is already come," he says, "when the sluggard intellect of this country will look from under its iron lids and fill the postponed expectation of the world with something better than the exertions of mechanical skill. Our day of dependence, our long apprenticeship to the learning of other lands, draws to a close. The millions that around us are rushing into life cannot always be fed with the sere remains of foreign harvests."

Benjamin Peirce a graduate of Harvard in the class 1829, had been concerned with the translation of the Mécanique Céleste, and was early familiar with the best mathematical thought of Europe. He became professor in Harvard College in 1833, and after the death of Bowditch, in 1838, he was easily the first mathematical astronomer in the country. His instruction was precisely fitted to develop superior intelligences, and this was his prime usefulness. Just such a man was needed at that time. Besides his theoretical researches on the orbits of the planets (specially Uranus and Neptune) and of the moon, his study of the theory of perturbations, and his works on pure mathematics and mechanics, he concerned himself with questions of practical astronomy, although the observations upon which he depended were the work of others. He was the consulting astronomer of the American Ephemeris and Nautical Almanac from its foundation in 1849, and its plans were shaped by him to an important degree. His relative, Lieutenant Davis, United States Navy (the translator of Gauss' Theoria Motus Corporum Coelestium, 1857), was placed in charge of the Ephemeris, and the members of its staff—Runkle, Ferrel, Wright, Newcomb, Winlock and others—most effectively spread its exact methods by example and precept. Professor Peirce undertook the calculations relating to the sun, Mars and Uranus in the early volumes of the Ephemeris. As a compliment to her sex, Miss Maria Mitchell was charged with those of Venus; Mercury was computed by Winlock, Jupiter by Kendall, Saturn by Downes, Neptune by Sears Walker.

The Smithsonian Institution was founded in 1846, and Joseph Henry was called from Princeton College to direct it. There never was a wiser choice. His term of service (1846-78) was so long that his ideals became firmly fixed within the establishment and were impressed upon his contemporaries and upon a host of younger men. The interests of astronomy were served by the encouragement of original research through subsidies and otherwise, by the purchase of instruments for scientific expeditions, by the free exchange of scientific books between America and Europe, and by the publication of the results of recondite investigations. It is by these and like services that the Institution is known and valued among the wide community of scientific men throughout the world.

But this enumeration of specific benefits does not convey an adequate idea of the immense influence exercised by the Institution upon the scientific ideals of the country. It was of the first importance that the beginnings of independent investigation among Americans should be directed toward right ends and by high and unselfish aims. In the formation of a scientific and, as it were, a moral standard a few names will ever be remembered among us; and no one will stand higher than that of Henry. His wise, broad and generous policy and his high personal ideals were of immense service to his colleagues and to the country.

The establishment of a national observatory in Washington was proposed by John Quincy Adams in 1825; but it was not until 1844 that the United States Naval Observatory was built by Lieut. Gilliss, of the Navy, from plans which he had prepared. By what seems to have been an injustice Gilliss was not appointed to be its first director.* This place fell to Lieut. M. F. Maury. Gilliss had been on detached service for some years, and a rigid construction of rules required that he should be sent to sea, and not remain to launch the institution which he had built and equipped.

* First edition, 1802. Sumner's method in navigation (1843) a very original and valuable contribution from a Boston sea captain, and Maury's Wind and Current Charts, begun in 1842, are two other notable contributions from a young country to an art as old as commerce.

The first corps of observers at Washington (1845) contained men of first class ability—Walker, Hubbard, Coffin. Gilliss' work as astronomer to Wilkes Exploring Expedition (1838-42), at his little observatory on Capitol Hill, had shown him to be one of the best observers, as well as one of the most assiduous. His study and experience in planning and building the Naval Observatory had broadened his mind. To the men just named, with Peirce, Gould and Chauvenet, and to their coadjutors and pupils, we owe the introduction of the methods of Gauss, Bessel and Struve into the United States, and it is for this reason that American astronomy is the child of German, and not of English science.

The most natural evolution might seem to have been for Americans to follow the English practice of Maskelyne and Pond. But the break caused by the war of independence, by the war of 1812, and by the years necessary for our youthful governments to consolidate (1776-1836) allowed our young men of science to make a perfectly unbiased choice of masters. The elder Bond (William Cranch Bond, born 1789, director of Harvard College Observatory, 1840-59) was one of the older school and received his impetus from British sources during a visit to England in 1815.

In estimating the place of the elder Bond among scientific men, it is necessary to take into account the circumstances which surrounded him. He was born in the first year of the French revolution (1789); he was absolutely self-taught; practically no astronomical work was done in America before 1838. When Admiral Wilkes was seeking for coadjutors to prosecute observations in the United States during the absence of his exploring expedition, he was indeed fortunate in finding two such men as Bond and Gilliss. Their assiduity was beyond praise, and it led each of them to important duties. Bond became the founder and director of the observatory of Harvard College, while Gilliss is the father of the United States Naval Observatory at Washington, as well as of that of Santiago de Chile, the oldest observatory in South America. Cambridge, though the seat of the most ancient university in America, was but a village in 1839. The college could afford no salary to Bond, but only the distinction of a title, "Astronomical Observer to the University," and the occupancy of the Dana house, in which his first observatory was established. His work there, as elsewhere, was well and faithfully done, and it led the college authorities to employ him as the astronomer of the splendid observatory which was opened for work in 1847. At that time the two largest telescopes in the world were those of the Imperial Observatory of Russia (Pulkova) and its companion at Cambridge. Each of these instruments has a long and honorable history. Their work has been very different. Who shall say that one has surpassed the other? We owe to Bond and his son the discovery of an eighth satellite to Saturn, of the dusky ring to that planet, the introduction of stellar photography, the invention of the chronograph, by which the electric current is employed in the registry of observations, the conduct of several chronometric expeditions between Liverpool and Boston to determine the transatlantic longitude, and a host of minor discoveries and observations.

Gilliss visited France for study in 1835, before he took up his duties at Washington. The text books of Bond and Gilliss were the astronomies of Vince (1797-1808) and of Pearson (1824-29). The younger Bond (George Phillips Bond, born 1825, Harvard College 1844, director of the Harvard College Observatory 1859-65) and his contemporaries, on the other hand, were firmly grounded in the German methods, then, as now, the most philosophical and thorough.

It was not until 1850, or later, that it was indispensable for an American astronomer to read the German language and to make use of the memoirs of Bessel, Encke and Struve, and the text books of Sawitsch and Brünnow.† This general acquaintance with the German language and methods came nearly a generation later in England. The traditions of Piazzi and Oriani came to America with the Jesuit Fathers of Georgetown College (1844), of whom Secchi and Sestini are the best known.

The dates of the foundation of a few observatories of the United States may be set down here. Those utilized for the observation of the transit of Venus in 1769 were temporary stations merely. The first college observatory was that of Chapel Hill, North Carolina (1831); Williams College followed (1836); Hudson Observatory (Ohio) (1838); the Philadelphia High School (1840); the Dana House Observatory, of Harvard College (1840); West Point (1841); the United States Naval Observatory (1844); the Georgetown College Observatory (1844); the Cincinnati Observatory (1845); the new observatory of Harvard College (1846); the private observatory of Dr. Lewis M. Rutherfurd in New York City (1848); the observatory at Ann Arbor (1854); the Dudley Observatory at Albany (1856); and that of Hamilton College (1856).

These dates and the summary history just given will serve to indicate the situation of astronomy in the United States during the first half of the present century. A little attention to the dates will enable the reader to place an individual or an institution on its proper background. It must constantly be kept in mind that the whole country was very young and that public interest in astronomical matters was neither educated nor very general. The data here set down will have a distinct value as a contribution to the history of astronomy in America. The developments of later years have been so amazing that we forget that the first working observatories were founded so late as 1845.

American science is scarcely more than half a century old. The day will soon come—it is now here—when we shall look back with wonder and gratitude to ask who were the men who laid the wide and deep foundations which already maintain so noble an edifice.

EDWARD S. HOLDEN.

Mt. Hamilton, Cal., April, 1897.

* He was, however, director during the years 1861-65.

† Dr. Bowditch learned to read German in 1818, at the age of 45.

ENGINEERING NOTES.

The fastest and longest run of a train hauled by an oil-fired engine is (says The Engineer) that of the Cromer express, on the Great Eastern Railway. Leaving Liverpool Street terminus at 1:30 P. M., this train arrives at Cromer—138 miles' distance—at 4:25 P. M., with but one stop at North Walsham, eight miles from Cromer, where it is due at 4.10. This gives a run of 130 miles in 160 minutes, or an average rate of 48·75 miles per hour. The train is regularly worked by the single driver express engine of Mr. Holland's standard design, and fired on his oil fuel system, and no similar fast train in the world is worked with such ease to the firemen.

Haulage ropes are generally made of steel wire, in Germany mostly of plow steel. According to a recent article in the Zeitschrift des Vereins Deutscher Ingenieure, ropes of aloe fiber may compete with steel, even for deep shafts. The aloe fiber is stronger and more elastic, but less flexible than manila hemp; its chief advantage is that it becomes stronger in damp places. The ropes have to be tarred, but, in spite of this circumstance, the corresponding lengths of rope which would break by virtue of their own weight are 12,000 for aloe and 12,500 for steel. In Belgian mines haulage by means of aloe ropes is quite common; great lengths are made with decreasing thickness.

General Wilson, chief of engineers of the army, has been making an examination of the report of the Mississippi River Commission and has brought to light some very interesting facts connected with the flood of last spring. It is shown that the flood of the Mississippi was the highest of which there is any record. The total length of the levees on both sides of the river was 1,377 miles, and there were in all thirty eight breaks by the flood, aggregating eight and seven-tenths miles. An interesting feature of the breakages is that none of the levees built by the United States government were broken, but the breaks occurred in those portions which had been built by States or municipalities or private persons. The Mississippi River floods will form an important part of the annual report of General Wilson, which is now in the course of preparation.

River dredging for gold is a new development in the mining industry which has attained a good deal of importance during the last two or three years, and dredges are now working successfully in the United States, in Georgia, Montana, Idaho and California. They have been especially successful in New Zealand. The amount of gold won in this manner in 1897 will be considerable, and next year it is likely to be still greater, the success of the dredges now employed being well established, and there being undoubtedly a good many places where they can be put to work to advantage. The idea is by no means a new one. As long ago as 1885 a company was organized to exploit the bed of the Atrato River, in Colombia, in this manner, but owing to defective apparatus, or perhaps to some extent to mismanagement, the undertaking failed, although there is reason to believe that the bottom of that river is rich in gold.

It sometimes happens in a machine shop that a piece of work is spoiled, or a tool broken, through not being stopped at a definite point in its progress. A simple piece of apparatus has just been devised which is applicable to any machine tool, and which stops the machine when a certain amount of work has been done. It consists of an electrical relay, which, when a current passes through it, releases a weighted lever, which shifts the belt and so stops the machine. At the same time an electric bell commences ringing to call the attendant's attention, the contact pointer is insulated from the machine bed, and the instrument is so placed that when the feed gear has moved the tool over the distance required it makes contact with either the slide rest or other moving part of the machine. A battery of a few Leclanché cells is sufficient to work several machines. This might prove a most useful labor saver, but as its object is to enable one man to look after two or three machines, its introduction is certain to be opposed by the workmen.

Engineering skill is likely to play an important part at Vladivostok, a prominent Russian port and the terminus of the Siberian Railway, but where for over four months the port is blocked up with ice, rendering shipping traffic impossible. For many years the Russian authorities have been endeavoring to overcome these natural difficulties, and some time ago ice breaking ships were introduced to break open the ice, an operation, however, which has proved practically useless. It is now reported that "a certain engineer" has proposed a plan for reclaiming the narrowest part of the Tartar strait between Saghalien and the Russian mainland. The theory of such an undertaking is that, if this is done, the cold current which enters the Japan Sea from the Arctic via Behring Strait will be checked, and the passage of the warmer tide, coming from the south through the Tshuma Strait, will make the water on the coast of Japan as warm as Vladivostok, and the latter will be warm all the year round. The expectation is entertained that this remarkable engineering work will be entered upon after the completion of the Siberian Railway.

In a new system of sinking shafts through quicksands and water-bearing strata by means of a freezing process, invented by Louis Koch, says The Engineering and Mining Journal, gaseous carbonic acid, ammonia, or a mixture of dioxide of sulphur, is circulated in specially constructed tubes, whereby a degree of cold of from 40° to 60° C. is generated and communicated to the ground. The freezing pipes are sunk through the bedrock, where the shaft is to be constructed, and this can be done in any direction and in any required number. Then they are connected with the condenser and the compressor, and a conduit is constructed for returning the expanded gases to the machine. The compressed gases become volatile on leaving the compressor in the connecting pipe, and take their course, directly or indirectly, as vaporous gas through apertures into the freezing apparatus, in order to enter into two separated conduits and thence into the various divisions of the apparatus and there to generate cold. The generation of cold thus takes place simultaneously and uniformly throughout the whole length of the combined apparatus.

ELECTRICAL NOTES.

The trains on the Bavarian railroads carry telephone receivers and transmitters, by which trainmen can at any time communicate with the nearest station.—Electrotechnische Rundschau.

In 1837, when it was proposed to erect a telegraph between St. Petersburg and Peterhoff, Schilling suggested as an alternative to a cable that the wires should be carried on posts, but one of the members of the commission said that "Wires in the air are truly ridiculous." Sixty years afterward the British authorities think so too.

The Italian Mediterranean Railway Company have, it is said, made a contract with the Electrical Company of North Italy to apply their electric brakes to both the passenger and goods trains between the stations of Bardonnechе and Modane on the Mont Cenis line. Should the trial be satisfactory, the whole of the line between Modane and Turin will be similarly equipped.

Workmen are now engaged in completing the installation of the electric light at the Houses of Parliament. Electricity reigns supreme in the dining rooms, lobbies, and corridors, and its use is gradually extending to the committee rooms. On the Peers' side, the Royal Gallery is being treated in a similar manner, and the dining room and grand committee room will be attended to in due time. Throughout the entire building there are no fewer than 5,000 lights.

The total length of the world's telegraph system has now reached 4,908,921 miles, exclusive of 180,440 miles of submarine cables. Of this Europe has 1,764,730 miles; Asia, 310,085 miles; Africa, 99,419 miles; Australia, 217,470 miles; and America, 2,510,548 miles. United States Consul Germain, who sends these figures to the State Department from Zurich, says they show that, notwithstanding the steady increase in the building of telegraph lines all over Europe, America leads the world and has almost double the European mileage.

A New York contemporary gives a description of a hoist magnet worked in connection with an electric traveling crane. The double-pole magnets in use at the plate mill of the Illinois Steel Company can handle with safety five tons, and only take about four ampères with a 250 volt current. After the magnet has been lowered on to a pile of plates, and several plates have been taken out together, the operator breaks the current for a moment, and one or two plates drop off at each break. It is said that enough residual magnetism remains in the plates next to the magnet to hold them until the current is again switched on. A concentric pole magnet has been constructed for handling hot plates and ingots, and there has been no difficulty in handling a 6,000 lb. or 8,000 lb. ingot at a low red heat.

The cable that is being laid between London and Birmingham for telegraphic purposes is making slow progress, and possibly the end of the century will arrive before it is in full use. It is not, it appears, to act as a substitute for the overhead wires, but is merely to augment the service and provide a means of avoiding the effects of storms. The new cable is being laid at a depth of about 2½ ft., and is described as of a kind which has not been used hitherto for telegraphic purposes, though it has been adopted to a great extent for telephonic services. Inclosed in a metal tube about 2 in. in diameter are 76 copper wires, and the novelty in the construction is that the wires are insulated from each other and from the sheathing by paper. Air passes between the wires and their wrappings, and assists in their insulation. It is thought that if the cable can be kept free from water, there is no likelihood that the paper will perish, and means to secure this freedom from damp are being taken while the cable is being laid.

A new railway signal is being tried on the Delaware, Lackawanna & Western Railroad, at Kingsland, N. J., U. S. A. The signal is peculiar, says The Electrician, in that the semaphore is pivoted at the center and revolves as an indication of safety. When it remains immovable it indicates danger. The semaphore arm is supported on a bracket fixed to the semaphore post and is operated by an electric motor. Placed on a spindle above the box containing the motor is a red signal lamp, which is obscured twice by each revolution of the blade, and the resultant flashes serve as a night safety signal. The continuous red light corresponds with the stationary arm day signal, and indicates danger at night. When the blade assumes the danger position it stands out horizontally, as do the ordinary semaphore signals. Two cells of storage battery are used for the operation of the motor and the track circuits. The cells are placed within a proper receptacle at the base of the semaphore post, and in the present instance have proved very satisfactory in operation. They are charged by a dynamo located in the railroad shops near by.

Most of the machinery in the Swedish iron ore mines is worked by electric power, and the installation at Grangesberg is the first long distance transmission of electric power in Sweden, says the Iron and Coal Trade Review, the distance from the Hellsjon Lake to Grangesberg being some 7½ miles. At Hellsjon, where the turbines are placed, there are three dynamos, one of 150 horse power and two of 100 horse power each, direct coupled to a turbine making 600 revolutions. The three phase current, of 150 volts pressure, is subsequently transformed into one of 3,500 volts. In addition to the above three generators there are two more 100 horse power dynamos, each in connection with a turbine; the one supplies a single phase current for lighting purposes, while the other can give either a three or a single phase current and is held in reserve. There are altogether twelve motors, varying in capacity from 45 horse power downward. Dynamite is used for blasting purposes, and is manufactured on the spot; the annual production is about 80 tons, of which half is used in the Grangesberg mines. The largest mine is the "Skarnlugen." Hitherto the ore has been put direct on to the trucks, but it is now broken at a lower level than that of the railway. The ore is separated from the rock in the mine; an electric ore separator is being installed. The bore holes are now larger (22 millimeters) and deeper than used to be the case, whereby less dynamite is required. The work is carried on night and day, electric light being installed.

MISCELLANEOUS NOTES.

A splendid deposit of copper has been discovered on the west coast of Newfoundland, says the Times. Analysis shows that the ore contains 83 per cent. of copper. It is located on the treaty shore, but can be worked through the new railway.

M. Michelin proposes to insert a clause in the next French budget for the withdrawal of copper coins of ten and five centimes from circulation and replacing them with nickel coins of twenty, ten, and five centimes. If the proposal is adopted, a total of 70,000,000 francs will be struck off. To avoid confusion with the silver currency the nickel coins will be pierced in the center and will have a smooth edge. They will be composed of 25 per cent. nickel and 75 per cent. copper.

The growth of the naphtha industry in Russia has been a rapid one. In 1870 the output of naphtha for the whole of Russia did not exceed 1,730,000 poods; in 1882 the yield was already more than 50,000,000 poods; ten years later, about 300,000,000 poods; and in 1894, 316,000,000 poods, of which 300,000,000 were obtained in the Baku government. Not all this immense quantity of naphtha is consumed by Russia alone, which has increased the export of naphtha and its products from 1,000,000 poods in 1881 to 60,000,000 in 1893.

More than 500,000 sewing machines are made in this country annually, which is 90 per cent. of the production of the world. Nearly 100,000 persons in one way and another make their living in this country out of sewing machines. In no branch of manufactures has a greater revolution been wrought by the sewing machine than in boots and shoes. In 1861 the first machine for sewing on soles was put into operation and a royalty of two cents on shoes exacted. By the aid of machines 350,000,000 pairs of shoes had been made up to 1877 in the United States, and probably an equal or greater amount in Europe.

A new use for peanuts is developing as the peanut butter industry becomes better understood. This product of the peanut answers in the place of ordinary butter for table use and is said to be excellent for shortening purposes, and for gravies, sauces, etc. In point of purity it is superior to the best dairy butter. It is well designed for the use of vegetarians who strenuously object to anything animal. There is already a considerable demand for this butter substitute, and it is very probable there will be an enlarged market for the nuts. At present the product of the United States is about 500,000 bags annually and that of the world is 600,000,000 pounds.—West Coast Trade.

Aluminum has replaced wood in parts of machinery, and it is also being used in place of rubber. The Waldo Foundry, of Bridgeport, Conn., has recently cast several thousand aluminum mouthpieces for graphophones. These were formerly made of rubber, but it is found that aluminum gives far better results, as it is more resonant. A very useful article made by the Waldo Foundry is chemical crucible tongs of aluminum. These are light and handy, and are not eaten by acids. Chemical tongs of other metals turn black, but a pair of aluminum tongs, used in the foundry laboratory for several years, are as bright as when first made.

Yankee ingenuity has produced a soapstone boot drier which should prove extremely useful in winter time. It consists of a block of soapstone, 8 by 2¼ by 1½ inches in size, attached to a wire bail for convenience in handling. There are grooves on the bottom running at right angles with each other, and holes which pass entirely through the block vertically to facilitate the escape of moisture. This commodity is designed largely for use in connection with rubber boots and shoes, leather boots, etc., and is especially recommended by the manufacturers for campers, lumbermen and others, who, by heating the stone and placing it in position after the footwear is removed, exhaust the moisture without injury to the fabric.—Philadelphia Record.

The Explosives Department of the Home Office has recently had under consideration the question of the restrictions to be applied to the manufacture and keeping of acetylene gas, and has conducted various experiments with the object of gaining information on this matter. The results show conclusively, Engineering reports, that acetylene gas when under a pressure of something less than two atmospheres is violently explosive; whereas at a pressure of less than 1½ atmospheres it appears to be reasonably free from liability to explosion, provided it is not admixed with oxygen or atmospheric air. For commercial and practical purposes it is considered sufficient to allow a pressure of 20 in. of water above that of the atmosphere (roughly about 1½ atmospheres), and it is accordingly proposed to draw the safety line at this point, and to declare acetylene when subject to a higher pressure to be an "explosive" within the meaning of the Explosives Act, 1875. In France and Germany, the authorities have fixed the limit of danger at 1½ and 1·1 atmospheres respectively, and have imposed prohibitions or restrictions on the keeping or manufacture of the gas when it is at a higher pressure.

Not so many improvements have characterized the process of coating cloth with rubber as have marked the progress of some other features in the application of that material in the arts. The chief solvents used in dissolving the rubber for coating purposes are naphtha, shale spirit, and benzol, these being mixed with purified solid paraffin by grinding together. Solubility is promoted by grinding or working; the raw or washed rubber is less soluble than that masticated or ground, and well ground rubber is more easily taken up than that which has been less worked. The washed rubber is for waterproofing, says the Boston Commercial Bulletin. The next operation is to grind the rubber and pigments together, run it out into a thin sheet and digest in naphtha, with a slight stirring as it is added, and the finishing is performed by dough mixers. The treatment of fabric which has to be done by spreading with the rubber consists in passing it through a pair of calenders, in order to press down knots and give a smooth and even surface, after which it is passed over a steam chest to expel moisture, it being now ready to receive the first coat. A little oxide of zinc or a little naphtha, which is retained by the rubber and which it gives up very slowly, is a drying which proves quite useful and prevents blistering in curing.

THE TRANS-SIBERIAN RAILWAY.

BEGUN in the month of May, 1891, the work of constructing the great Trans-Siberian Railway has been pursued with what may be called feverish haste. Such haste, although excessive, is nevertheless preferable to too great dilatoriness. After deciding to undertake the work, the Russian government immediately got at it, and it is certain that the Asiatic transcontinental will be completed within the time originally fixed. On the day upon which the last rail has been bolted, the new railway, although inadequate for an extensive traffic, and not as yet possessing all of its commercial utility, will nevertheless possess all of its political importance. The two extremities of the Czar's immense empire will be closely connected, a route to China will have been created, and Russia, mistress of such route, will improve it at her leisure.

At the end of last year the trains starting from TchelIabinsk were already running as far as to Krasnoiarsk. This city, of rich and flourishing aspect, is destined for considerable development. An English company, which has recently established entrepots here, is bringing in by ocean and river large quantities of products of English manufacture, principally linen and cotton goods.

At the end of January the section from Krasnoiarsk to Kainsk was open to the running of trains. From Kainsk to Kloutchi, too, the road is finished, but trains are running thereon only irregularly.

The section of the line that is to run around Lake Baikal from Irkoutsk to Mysovsk is for the moment entirely neglected. The government has decided to postpone the construction of the railway in this rough and mountainous region, the cost of which, it is calculated, would be $80,000 per mile. The project is to employ large ferry boats of the American type, powerful enough to break the ice in winter, for carrying the trains from one shore of Lake Baikal to the other. These boats, gaging 4,000 tons, will be provided with two screws driven by a 3,750 horse power steam engine. They will be capable of carrying a train of twenty-five cars at a speed of about fifteen miles an hour, and will consequently take three hours to cross the lake.

In order to reach Lake Baikal from Irkoutsk, one ascends the river Angara. In winter this river is frozen over at Irkoutsk, as is also the lake for its entire extent. Nevertheless, starting from the Baikal, for a length of from six to nine miles, the river never freezes. This curious fact must be attributed both to the swiftness of the current at this place and to the relatively high temperature of the deep water of the lake, which is fed by a large number of warm springs.

The work on the railway is being resumed at Verkhne Oudinsk through Transbaikalia. As far as to Tchita it is not far advanced, but from Tchita to Nertchinsk it is being pushed with the greatest activity. This important section will be opened to exploitation during the course of next year.

The line of Manchooria, designed to replace the north-south. This section, which is called the Oussouri Railway, has just been completed, but it is not probable that the exploitation of the line can be begun for several months yet.

In leaving Khabarovka, the direction line follows for 270 miles the right bank of the Oussouri, the left bank of which belongs to Chinese Manchooria. The valley of the Oussouri is narrow. This river, all along its course, receives numerous torrents and a few affluents of a certain importance, separated from each other by high offshoots of the Sikhota chain of mountains. No part of the Trans-Siberian necessitated so many bridges and cuttings and so much filling in. It has been possible, however, to avoid the construction of tunnels. In this valley, moreover, an enormous amount of rain falls every year. Inundations are frequent, and wherever the railway approaches the bed of the Oussouri important sustaining walls have had to be built in order to protect it.

Three of the bridges over the affluents of the Oussouri are 840 feet in length. These are those of the rivers Khor, Bikin and Ima. Like the rails, the bridge iron came from the Russian works of the Oural and Donetz. As the superstructure of these bridges could not be of a single span, it rests upon two stone piers. The establishment of a masonry pier in the bed of a Siberian river, such as the Ima, which is immeasurably swollen at the time of the melting of the snow or as a consequence of torrential rains, and which is covered for four months with thick ice, required special pro-

CRIMINALS WORKING UPON THE TRANS-SIBERIAN RAILWAY UNDER THE SUPERVISION OF SOLDIERS.

Kloutchi is now the terminus of the Trans-Siberian of the west, and we have just learned by telegraph that Khabarovka has, for some days, been the terminus of the Trans-Siberian of the east, or the Oussouri Railway, the head of the line of which is Vladivostok. From Kloutchi to the Oussouri, that is to say, from the center of Russian Asia to the shore region of the Pacific, nearly a hundred thousand laborers are busily engaged upon the colossal work. Some of these, such as the blacksmiths, carpenters, etc., are free workmen, while others, who are employed upon rough work, such as digging trenches, filling in, carrying wood and iron, etc., are criminals who are closely watched by soldiers. On the west and east sides the rails are being rapidly laid and the sections constructed simultaneously at a large number of points are being connected. Strietensk and Khabarovka, which were connected during the summer by steamboat service upon the river and its affluent, the Chilka, will be the two provisional extremities of the line.

Between Kloutchi and Irkoutsk the work is far enough advanced to allow it to be seen that in January, 1898, travelers starting from Moscow or St. Petersburg will reach Lake Baikal without leaving the cars. Along the postal road from Irkoutsk to Krasnoiarsk travel innumerable caravans, some bringing into Russia bales of tea that have come from China through Kiakhta, and others carrying to Irkoutsk European merchandise from the entire region of the Baikal. Such animation is a good omen for the traffic of the railway.

Strietensk Khabarovka section, will make a connection between the cities of Nertchinsk and Strietensk.

Strietensk, upon the Chilka, and Khabarovka, upon the Amoor, would be connected by an admirable water way if the Siberian winters were not so severe. Unfortunately, the Amoor and its affluent the Chilka are free from ice only from May to September. Navigation, therefore, lasts but four months, or five at the most; but during this very short period it is very active.

Upon the Amoor, at a nearly equal distance from Strietensk and Khabarovka, at the mouth of the river Zeia, which comes from the country of gold mines, there has been built an important and growing city. This is Blagovestchensk, which is both a mining center and a fluviatile port of the first rank. The complete melting of the snow and breaking up of the ice in the river take place here toward the middle of May. It is then that the city is busiest. Numerous boats daily arrive and start and ascend or descend the Amoor. The majority are now occupied in the carriage of rails and other materials designed for the railway. The Transsiberian, until it is finished, will thus absorb the entire activity of Siberia.

One of the boats that descend the river takes us to Khabarovka, at the confluence of the Amoor and Oussouri. Khabarovka, which is a military city, is the residence of the governor general of the three provinces of Transbaikalia, Amoor and Littoral. Thence to Vladivostok, the railway leaves its general direction from west to east, in order to take a direction exactly

cesses. It was necessary to take advantage of the period of congelation of the water. The materials were easily carried upon the ice by means of sleighs. Around the site of the pier foundations, upon the frozen surface, was constructed a wooden house for the workmen, and it was in the interior of this, protected from the cold, snow and storms, that they did their work. When the period for the ice to break arrived, they removed their improvised shop, but the pier remained ready for the reception of the long metallic superstructure.

Upon the river Ima is situated the little village of Iman, where but yesterday stopped the trains coming from Vladivostok, and which thus acquired a certain temporary importance. It was here that was unloaded the merchandise for transshipment upon boats that afterward reached the Amoor in descending the Oussouri. The boats that did the carrying were those that had brought either to Iman or to the different points situated between Khabarovka and Iman the materials taken aboard at Nikolaievsk, a seaport at the mouth of the Amoor and designed for the construction or exploitation of the railway.

From Iman station to that of Vladivostok the line (upon which trains have been running since 1895) is 265 miles in length. The locomotives were, almost all of them, purchased in the United States. As for the cars, they came for the most part from the great Russo-Baltic works of Riga. A few of them were purchased at Vladivostok.

At 37 miles from Iman the line crosses the Oussouri

upon a new bridge. To the west it leaves Lake Khanka, a simple permanent inundation called by the Chinese Khun-Khat, or "Mediterranean." Then the road follows the valley of the river Lefou, which falls into this lake not far from the station of Nikolskoie, which is destined to become the head of the line of

BRIDGE OVER THE OUSSOURI, 288 MILES FROM VLADIVOSTOK.

the Manchooria Railway. After leaving this station, which is 83 miles distant from Vladivostok, the line enters the valley of the river Soulfoun. The inundations of this little affluent of the Sea of Japan are far more dangerous than those of the Oussouri. The line along the side of the mountain had been insufficiently studied, and the exploitation had hardly been begun when the engineers perceived that an entire section, constructed upon loamy earth, at about 50 miles from Vladivostok, was slowly descending into the Soulfoun. Such sliding could only be arrested at the cost of important works that have been but recently finished. Could this valley, so beset with obstacles, be avoided? Competent men think that it could, and adversely criticise the direction line that was adopted between

BRIDGE OF THE RIVER LEFOU, AT 100 MILES FROM VLADIVOSTOK.

Vladivostok and Nikolskoie, in that it causes the railway to run a greater danger than that of the inundations from above and slidings from below, since twelve miles before reaching Vladivostok the line runs along the shore of the bay of Peter the Great, and in case of war it would be easy for the ships of an enemy to bombard the track, and thus cut off the communication of Vladivostok with the valleys of the Oussouri and the Amoor. Such considerations, it is said are capable of determining the abandonment of the present line and the selection of a new one nearer to the east.

The general rules laid down for the entire Transsiberian have naturally been applied to this eastern section. The track is single and the most distant stations are 23 miles apart. Three trains a day are run in each direction.

"Vladivostok! all out!" It would not be commonplace to hear this cry on the evening of the tenth day passed in a car of this monster Oriental Express that the Trans-Siberian train will be. But it is only in France that travelers are thus notified as to what they have to do by the indistinct yells of men appointed for the purpose.

Vladivostok, the name of which signifies "Ruler of the East," and which has been developing for the last two or three years with a rapidity seen only in American towns, was founded in 1861 at the extremity of a peninsula that divides the bay of Peter the Great into two parts. This peninsula is continued by a group of islands, the principal of which is Kozakovitch. The strait that separates this island from terra firma has received the name of the Eastern Bosphorus. It is in the center of this strait that has been built the city of Vladivostok surrounded with verdant hills, which themselves surround one of the finest natural ports in the world, called by the Russians the Golden Horn.

Vladivostok is not yet, but may hope to become the Constantinople of the Far East. Its climate, without resembling that of Marseilles, which is in the same parallel, is not so severe as might be supposed. Like the port of Odessa, the Golden Horn is blocked by ice for only a month and a half or two months in the year.

Two Russian ports upon the Pacific now divide between them the importations of European merchandise—those of Vladivostok and Nikolaievsk. The latter, although closed for six months of the year, has for a long time been able to benefit by its situation at the mouth of the river Amoor, which carries the imported products into the interior. Nevertheless, in recent years, the supremacy of Vladivostok has become indisputable, and the completion of the Transsiberian and opening of the Transmanchoorian will definitely consecrate it.

The vessels that the Golden Horn receives bring to Siberia linen and cotton goods from England, the same goods, but in ordinary quantities, along with tobacco, sugar and alcohol, from Russia, glass and table utensils from Belgium, flour, machines and farming implements from the United States, agricultural products from Corea, fruit and rice from Japan, etc. The exportations from Vladivostok, which up to the present are not of much importance, consist of furs and especially various products derived from the whale and seal fishing.

The commerce of the city is concentrated in the hands of foreigners in the proportion of 75 per cent. Of the business about 30 per cent. is done by Germans, about 13 per cent. by English and Germans, 12 per cent. by Chinese and 5 per cent. by Americans.—L'Illustration.

THE DETERRENT INFLUENCE OF MODERN ARMS.*

By Gen. O. O. HOWARD, U. S. Army (retired).

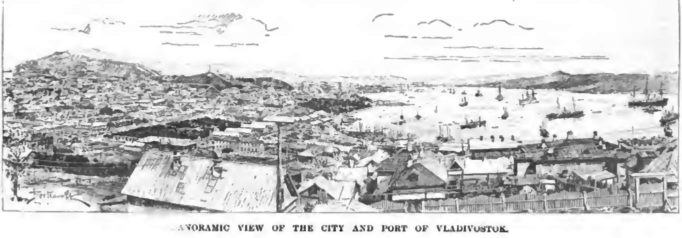
IT is now a common thought, regardless of the spurs of religion, which probably are as active to-day as ever in history, and one independent of the blessings attendant upon peace makers and peace seekers everywhere, that the modern improvements in arms, arrangement and methods of war will have, nay, have already had, a strong deterrent effect against war upon all the civilized peoples and governments of the world.

It is said by one of our scientific thinkers that all anger thought and fear thought come from mental germs of abnormal growth, and that they can be and should be torn up by the roots and cast away. I am of the mind, judging from passing events, that the day has not yet come for this; and that fear and anger will remain for some time to be quite generally predicable of human souls and of nations. Certainly while fear continues, battle and war will excite it, as they always have done; and more and more will be the apprehension as the probability of perishing in a conflict increases. The soldier cannot help seeing and knowing the facts of extreme danger; and even if he be brave enough to take desperate chances or march to certain death, still his government or the people back of it will be unwilling to make the sure sacrifice of his life.

The rifle now used in our regular army, named the United States magazine rifle, was adopted in 1892. The weight of the weapon is nine pounds, having a caliber of 0·31 of an inch. Its sight is graduated for a range of 1,900 yards, but it can be fired easily 3,000 yards. Its bullet has a weight of 220 grains. Its flight is swift and almost noiseless. The smokeless powder renders the place from which it starts impossible of discovery by observing enemies. When it strikes the hardest wood its effect is several times greater than that of any rifle which we used in the late war. Think of those experiments with this rifle at our proving grounds, where block after block of pine lumber, each an inch in thickness, was added till there was an obstruction of four feet. Those little steel-headed projectiles, sent from a gun a thousand yards away, easily passed through the blocks without injury to themselves. Three feet of oak fared no better, while even iron plate three-quarters of an inch in thickness suffered a like perforation. I remember the grim effect upon my young heart more than forty years ago when I first saw a riddled target, and was asked by a companion how I would like to stand that racket. This modern firing is considerably worse and done at once. By observation it is found that men's arteries are severed as if cut by the lancet and the bones are comminuted as if dried and pounded in a mortar, and yet the bullets themselves receive little or no injury. Ours is a magazine gun and supplies five cartridges at a time. This is the rifle with which a soldier may easily hold his aim and send twenty bullets against the target or an adversary each minute. Should he desire to fire without aiming, the number of shots may be doubled. His only limit in destructiveness will be found in the size of the ammunition load which he can carry.

Should an enemy in close formation come near a company, say of not to exceed twenty men, the members of that company could easily dispose of, by death and wounds, from eight to ten thousand men in less than an hour's time. It is not likely that just this arrangement could ever be made for twenty marksmen, but I offer this object lesson to indicate the effects of this modern

* From The Independent.



ANORAMIC VIEW OF THE CITY AND PORT OF VLADIVOSTOK.

arm. With an intrenched regiment having this United States magazine rifle, a regiment of a thousand men like the Third Maine, the Second Massachusetts, the Second Vermont or the Ninth Indiana of our war, whose prowess in action I so often observed or knew of, a skillful colonel would be able to hold his ground against any successive rushes which ten thousand men could make. With plenty of ammunition, a star fort, having its approaches properly earth covered and its parapet guarded by such rifles, could not be taken by assault. Had Lee's troops been thus armed at Fredericksburg, every man of ours who passed beyond the line of the city houses and approached the Marye Heights would have fallen, and Burnside could not with his army have recrossed the Rappahannock.

I notice that the Hotchkiss rifle, a field cannon, has been much experimented with at our proving grounds, and is in our service in both army and navy. Its trials varied from 100 to 4,000 yards. The weight of the powder in a charge is about two pounds, and the length of the cartridge complete is 19 inches; the shell is steel. In firing for rapidity and with accuracy at 4,000 yards, ten shots were fired with but one miss. The ten rounds were fired in 2 minutes and 26¾ seconds. At one mile range were fired ten shots, again with but one miss, all in 1 minute and 33½ seconds. This gun easily sends its projectile a distance of five miles.

What is called the six pounder Maxim-Nordenfelt gun, or some slight modification of it, is the one about which so many inquiries are made in the journals of the day. We have had this gun under trial since 1894, firing it with rapidity and accuracy through different ranges. The provers began with one sighting shot, then delivered ten shots without a miss. The deviations from the middle of the target were inconsiderable. This was accomplished in 2 minutes and 37¼ seconds for a one mile range. For a three mile range three trials were allowed for the sighting, then ten shots quickly followed at the target and all hit. The caliber of this cannon is 2·244 inches. The estimated time is 20 rounds per minute, or 65 rounds in three minutes. The Germans called the field pieces to which I refer, after making their own improvements upon them, "the model of '73 and '78," the caliber being 88 millimeters (3·3 inches). During 1890, the Germans succeeded still further with these field guns and their carriages, making progress. Their new gun is now denominated the model of '91. They have secured elasticity of metal and increased tenacity, thus eliminating, as far as possible, dangers from breakage and bursting, which, of course, always had immediate deadly effects upon their own artillerymen, and could not help causing widespread apprehension and terror among them. And again, in their carriages and ammunition wagons made for these guns they have secured greater lightness, and are now in these respects considerably ahead of the French.

The smokeless powder will aid much both the French and the Germans in gaining for themselves a prospective morale over a foe not so well furnished—a foe having only other kinds of powder. It is interesting to observe the efforts made by German officers to have exploding shells give some plain signs of where they strike. I am reminded of our own efforts in the war to read the enemy's signal code. The German artillerists, using the smokeless powder in their cannon, "put 300 balls into the shell, and in the interstices of these balls they introduce a powder whose composition is a secret;" that is to say, thus far secret. The French can analyze, and so can our chemical experts. That new explosive mixture is colored. The impact and explosion of these shells can, now, from the flash, be easily detected by a field glass at a distance of three miles. We shall soon be abreast of other armies in such things as these colored flashes, enabling the battery officers to measure length of range and discover far-off points of danger and obstacles to be overcome. No one can exaggerate the effect of a battery thus equipped, after the range shall be ascertained—its effect against infantry, cavalry or inferior artillery. Troops in open ground without cover, so withstood, must give way or be practically annihilated.

THE WORSHIP OF METEORITES.*

HERE is a small fragment of iron that has a curious history. It is a portion of a mass of meteoric iron found upon a brick altar in one of the Ohio mounds. Along with it were various objects—a serpent cut out of mica—several terra cotta figurines—two remarkable dishes carved from stone into the form of animals; pearls, shells, copper ornaments and nearly three hundred ankle bones of deer and elk. There were but one or two fragments of other bones, and one animal furnished but two of these ankle bones; hence they must have been selected for some special, important reason. The figurines had been apparently broken for some purpose, and the whole collection had suffered in the fire not a little. In a like altar of another mound of the same group were found nearly two bushels of like objects.

It must have been in some ceremony of a religious, possibly one of a funereal, character that the mound builders collected hereon the altar their ornaments and other valuables, and after burning them buried the charred débris in the huge earthen mound that was built over them and the altar.

What would we not give if this fragment could be endowed with the power of repeating to us its experience—chapters in the history of that people? But nearly all that we can say is that it was found among objects held by them in peculiar esteem, and used by them in some serious, probably religious ceremony.

There was formerly, and so far as I know there is still, in the collection of meteorites in Munich, a stone that weighs about a pound. It fell in 1853 in the region north of Zanzibar, on the East African coast, and was seen and picked up by some shepherd boys. The German missionaries tried to buy it, but the neighboring Wanikas, because it fell from heaven, took it to be a god. They secured possession of it, anointed it with oil, clothed it with apparel, ornamented it with pearls, and built for it a kind of temple to give it proper divine honors. The agents of the missionaries were not allowed even to see the stone, far less could they purchase the Wanika's tutelar deity. Neither entreaties, nor arguments, nor offers of the missionaries, nor of the officials were of any avail. But when three years later the wild nomad tribes of the Masai came down upon the Wanikas, burned their village, and killed large numbers of them, the Wanikas thought very differently of the stone's protecting power. In fact, they lost all respect for it. A famine having meanwhile arisen, the elders of the tribe were quite ready to exchange their palladium for the silver dollars of the missionaries.

Among the Buddha legends is one of two merchants who offered food to the Buddha, which was accepted, and in consequence of their request for some memorial of him the Buddha gave them a hair and fragments of his nails, and told them that hereafter a stone should fall from heaven near the place where they lived, and that they should erect a pagoda and worship these relics as though they were Buddha himself.

The nations of India have always been specially superstitious about stones fallen from the skies. In 1620 an aerolite fell near Jullunder, and the king sent for a man well known for the excellent sword blades that he made, and ordered him to work the lump into a sword, a dagger and a knife. The mass, however, would not stand the hammer, but crumbled in pieces. By mixture with iron of the earth the required weapons were made.

In 1867 a shower of stones fell, some forty in number, at Saonlod. The terrified inhabitants of the village, seeing in them the instruments of vengeance of an offended deity, set about gathering all they could find, and having pounded them into pieces, they scattered them to the winds.

In 1870 a meteorite fell at Nidigullam, and the Hindoos at once carried it to their temple and worshiped it. The same has been repeated in India on the occasion of several stonefalls in the present century. One native ruler refused to allow a stone to be carried across his territory for fear of the injury that might come to his people or his lands.

Two Japanese meteorites, formerly the property of a daimio family, were long kept and handed down as heirlooms, being in the care of the priests in one of the family temples. They were among the family offerings made to Skokujo on her festival days. They were connected with her worship by the belief that they had fallen from the shores of the Silver River, Heavenly River, or Milky Way, after they had been used by her as weights with which to steady her loom. One of these stones was presented by its late owner to the British Museum, and it is in its collection of meteorites.

There is a curious institution among the Chinese that has existed, according to Biot, from a time more than one thousand years before Christ. The Chinese attributed to different groups of stars a direct influence upon different parts of the empire. Some of these groups correspond, for example, to the imperial palaces, to the rivers, the roads and the mountains of China. By reason of this belief, regular observations are made by the imperial astronomers of all that passes in the heavens, especially of the groups of stars in which comets and meteors originate, or across which they travel. The interpretation of what is seen in the sky forms part of the duties of these very important officials. These observations have been carefully written out, and are preserved in the archives of the empire. Upon the ending of a dynasty, by change of name or otherwise, these comet and meteor records have been published as a special chapter of the chronicles of the dynasty. The existing dynasty began in 1647, since which date the records are, therefore, unpublished.

In 1492 a stone of 300 pounds weight fell at Ensisheim, in Alsace. The Emperor Maximilian, then at Basel, had the stone brought to the neighboring castle, and a council of state was held to consider what message from heaven the stonefall brought to them. As a result, the stone was hung up in the church with an appropriate legend, and with strictest command that it should ever remain there intact. It was held to be an omen of import in the contest then in progress with France and in the contest impending with the Turks. Nineteen years later a shower of stones fell near Crema, east of Milan. The Pope was at war with the French, and the stones fell into the French territory. Before the year had passed the French, after a long possession of Lombardy and serious threatening of the States of the Church, were forced to retire from Italy. At this time Raphael was painting for an altar piece his magnificent Madonna di Foligno, now in the Vatican. Beneath the rainbow in the picture, indicating divine reconciliation, Raphael painted also this Crema fireball, apparently to set forth divine aid and deliverance.

I have thus rapidly gone over some selected facts, showing how the mound builders, the wild Africans, the Hindoos, the Japanese, the Chinese, the modern Europeans, have been ready to revere these mysterious bodies that come from the skies. But it is in the Greek and Latin literature that we have reason to expect the more numerous and full accounts, both legendary and historic, of this reverence and worship.

It is now, I believe, admitted by the best scholars that both in Greece and in Italy there was a period, earlier than the age of images, when the objects worshiped were not wrought by hand. Men worshiped trees and caves, groves and mountains, and also unwrought stones. Even after men began to make their objects of worship, these were in many cases mere hewn stones, not images. The earlier Greek term *ἄγαλμα*, an object of worship, stands apart from the latter term *εἰκών*, image.

What would be more natural in that age to the affrighted witnesses of the most magnificent of spectacles, the fall of a meteorite, than for them to regard the object which had come out of a clear sky, with terrific noise and fire and smoke, as something sent to them by the gods to be revered and worshiped? It was nobler to worship a stone fallen from the sky than one of earthly origin.

The worship of an unwrought stone once established has wonderful vitality. For example, the Greek writers speak of such a worship in their day among the Arabian tribes. When Mohammed, with his intense iconoclasm, came down upon Mecca and took the sacred city, he, either for reasons of policy or from feeling, spared the ancient worship of this black stone. Entering into the sacred inclosure, he approached and saluted it with his staff (where it was built into the corner of the Kaaba), made the sevenfold circuit of the temple court, returned and kissed the stone, and then entered the building and destroyed the 360 idols within it. To-day that stone is the most sacred jewel of Islam. Toward it each devout Moslem is bidden to look five times a day as he prays. It is called the Right Hand of God on Earth. It is reputed to have been a stone of paradise, to have dropped from heaven together with Adam. Or, again, it was given by Gabriel to Abraham to attest his divinity. Or, again, when Abraham was reconstructing the Kaaba, that had been destroyed by the deluge, he sent his son Ishmael for a stone to put in its corner, and Gabriel met Ishmael and gave him this stone. It was originally transparent hyacinth, but became black by reason of being kissed by a sinner. In the day of judgment it will witness in favor of all those who have touched it with sincere hearts, and will be endowed with sight and speech. The color of this stone, according to Burckhardt, is deep reddish brown, approaching to black; it is like basalt, and is supposed by some to be a meteorite.

It is not important for my purpose to separate the history from the myth. Eusebius quotes from an old Phœnician writer, Sanchoniathon, that the goddess Astarte found a stone that fell from the air, that she took it to Tyre, and that they worshiped it there in the sacred shrine. We have reason to question whether that Phœnician writer ever lived. What matters it? The existence of the story in Eusebius' time has to us a significance not greatly unlike that of the existence of the worship itself in the earlier years.

Virgil describes a detonating meteor in such terms that I feel reasonably sure that either he had seen and heard, or else he had had direct conversations with others who had seen and heard a splendid example of these meteors. The passage is in the second book of the Æneid. The city of Troy was captured and was burning. All was in confusion. The family of Æneas was gathered ready for flight, but Anchises would not go. An omen, lambent flames on the head of his grandson, began only to shake his purpose to perish with his country. He prayed for more positive guidance. It is Æneas who describes the scene:

"Hardly had the old man spoken when across the darkness a star ran down from the sky carrying a brilliant light torch. We saw it go sweeping along above the roof of the house. It lighted up the streets, and disappeared in the woods on Mount Ida. A long train, a line of light, remained across the sky, and all around the place was a sulphurous smell. A heavy sound of thunder came from the left. Overcome now, my father raised his hands to heaven, addressed the gods and worshiped the sacred star. 'Now, now,' he cried, 'no longer delay.'"

This story is, of course, all legendary, but Virgil's description of the scene is true to life as conceived by pagan Rome in his day.

The images that fell down from Jupiter, or that fell from the skies, are often spoken of by Greek and by Latin writers. I mention three or four cases only where this allusion points to a meteoric origin as possible or probable. The earliest representative of Venus at old Paphos, on the island of Cyprus, was one of these heaven-descended images. It was not the Venus of the Capitol, nor the Venus of Milo, but as described was a rude triangular stone.

Cicero, in the grand closing passage of his oration against Verres, calls upon Ceres, whose statue he says was not made by hands, but was believed to have fallen from the skies. The earliest of the images of Pallas at Athens was said to have had a like origin. Pausanias saw at Delphi a stone of moderate size which they anointed every day, and covered during every festival with new shorn wool. They are of opinion, he adds, respecting this stone, that it was the one given by Cybele to Saturn to swallow as a substitute for the infant Jupiter, which Saturn after swallowing vomited out on the earth.

There is a marvelous story of a peculiar stone in the poem Lithika by the apocryphal Orpheus. Phœbus Apollo gave the stone to the Trojan Helenus, and Helenus used it in soothsaying. It was called Orites, and by some Siderites. It had the faculty of speech, and when Helenus wished to consult it he performed special ablutions and fasts for twenty-one days, then made various sacrifices, bathed the stone in a living fountain, dressed it and carried it in his bosom. The stone now became alive, and to make it speak he would take it in his arms and dandle it, when the stone would begin to cry like a child for the breast. Helenus would now question the stone, and receive its answers. By means of these he was able to foretell the ruin of the Trojan state. Whoever framed that story had, I believe, before him a real stone, and the description is very like that of a meteorite, saying nothing of its having come from Apollo. The Orphic writer says that it was rough, rounded, heavy, black and close grained. Fibers like wrinkles were drawn in circular forms over the whole surface above and below.

Here I show you a stone such as was described—rounded, black, heavy, close grained and having fibers like wrinkles in circular forms over the whole surface above and below.

The name Siderites was at a later date applied to the loadstone, but by this writer the two stones are separately described, and are apparently distinct. If this name was of Greek origin, it seems to be allied to sideros, iron, and this heavy stone, like nearly all meteorites, probably contained iron. If, however, this name came from a Latin source (for it is used both by Greek and by Latin writers), it has affinities with Sidus, a star, and its meteoric character is still more clearly indicated.

One of the most interesting of the stories about images that have fallen from heaven is the basis of that beautiful tragedy of Euripides, "Iphigeneia in Tauris." To many of you the story is familiar, but it will bear repetition.

The goddess Diana detained at Aulis the Grecian fleets by contrary winds, and required the sacrifice of Iphigeneia, the daughter of Agamemnon, before the Greeks could set sail. The father consented; and the daughter, apparently sacrificed, was really rescued by Diana, and borne to the Tauric, or Crimean peninsula on the north shore of the Black Sea. She was then made a priestess in the temple of the goddess. At this shrine the barbaric inhabitants used to sacrifice before an image of Diana, that fell from heaven, all strangers that were shipwrecked upon the coast. The unhappy

* A lecture delivered in New Haven, Conn., by the late Prof. Hubert A. Newton. (Reprinted from the American Journal of Science.)

Iphigeneia, forced to take a leading part in these human sacrifices, laments her sad lot:

"But now a stranger on this strand,
'Gainst which the wild waves beat,
I hold my dreary, joyless seat,
Far distant from my native land;
Nor nuptial bed is mine, nor child, nor friend.
At Argos now no more I raise
The festal song to Juno's praise;
Nor o'er the loom sweet sounding bend,
As the creative shuttle flies,
Give forms of Titans fierce to rise,
And dreadful with her purple spear
Image Athenian Pallas there.
But on this barbarous shore
Th' unhappy stranger's fate I moan,
The ruthless altar stained with gore,
His deep and dying groan;
And for each tear that weeps his woes,
From me a tear of pity flows."

Orestes, the brother of Iphigeneia, had avenged upon his mother the murder of his father. For this he was driven by the Furies. While stretched before the shrine of Phœbus he heard the divine voice from the golden tripod, commanding him to speed his way to the wild coast of the Taurians, thence to take by fraud or by fortune the statue of Diana that fell from heaven, and carry it to Attica. Doing this, he should have rest from the Furies.

He was captured, however, along with his friend Pylades, and brought to the altar to be sacrificed. The relationship of the brother and sister became here revealed, and they together fled, carrying with them the image. It was not without a struggle that they reached the shore, but finally,

"On his left arm sustained
Orestes bore his sister through the tide,
Mounted the bark's tall side and on the deck
Safe placed her and Diana's holy image
Which fell from heaven."

Neptune favored the Greeks, Minerva forbade pursuit, and the image was borne to Halae (or as some said to Brauron) in Attica.

Cicero spoke of the Trojan Palladium as something that fell from the sky: quod de coelo delapsum. Other classical writers, notably Ovid, speak of it in similar terms. The story in its various forms points toward a stonefall as its basis. One form of it runs thus:

Pallas and her foster sister Athena were wrestling with each other, when Pallas was accidentally killed. In grief Athena made an image of Pallas and set it up on Olympus. When King Ilus was about building his city on the Trojan plain he prayed for a favorable omen. In response to his prayer Jupiter cast this image down at the feet of the suppliant king. In the new city it was set up in a temple specially erected to contain and protect it. So long as Troy could keep safely this image, the city, it was firmly believed, could not be taken by its foes.

According to one story, the Greeks stole the image before capturing the city. As many cities afterward claimed to possess the treasure as claimed to be the birthplace of Homer. According to the Romans, Æneas carried the Palladium to Italy, and the image was regarded as the most sacred treasure of the Roman state. For centuries even in historic times it was so carefully kept by the Vestal Virgins that the Pontifex Maximus was not allowed to see it.

We naturally have doubts about the nature, or even the existence, of an object so kept out of sight. What it was that the Vestals thus guarded, or whether they had anything to represent the image of Pallas, will probably never be known. But it is far otherwise with another famous object of Roman worship. To the east of the Trojan plain on which the Palladium fell rise the mountains of Phrygia and Galatia. In Pessinus, near the border line of these two countries, and in the caves and woods near Pessinus, the goddess Cybele, the mother of the great gods Jupiter, Neptune and Pluto, was specially worshiped. This worship may not have been more degrading than the worship of many other Asiatic divinities. But it was wretched and unmanly almost beyond our possible conception. It furnished to Catullus the theme for the most celebrated of his poems, one of the strongest pictures in all literature. The Grecian athlete entered her service with joyful music and dancing. Too late he looks back from the Asiatic shore, out of his hopeless degradation, on the nobleness of his former Grecian life. The lion of Cybele drives him in craven fear again into the wild woods to spend his days in the menial servitude. The Roman poet exclaims, "O goddess, great goddess Cybele, goddess queen of Dindymus; far from my house be all thy frenzies; others, others, drive thou frantic!"

At some unknown early time a meteoric stone fell near to Pessinus. It was taken to the shrine of Cybele and there set up and worshiped as her image. This image and its worship very early attained a wide celebrity. About two hundred years before Christ, in the time of the second Punic war, the stone was transported to Rome. The detailed history of the transfer is given by several writers in varied terms. It forms one of Livy's charming stories, it is told in poetic terms by Ovid, it is given as a tradition by Herodian. For every detail of the history I do not ask confiding belief, but the principal event is, I suppose, historically true.

In the year 205 before Christ, Hannibal had, since crossing the Alps, been holding his place in Italy for more than a dozen years, threatening the existence of the Roman state. The fortunes of war were now somewhat adverse to the Carthaginian general. A shower of stones alarmed the Romans. The decemvirs consulted the Sibylline books and there found certain verses which imported that whensoever a foreign enemy shall have carried war into the land of Italy, he may be expelled and conquered if the Idæan mother be brought from Pessinus to Rome. These words were reported to the Senate. Encouraging responses came at the same time from the Pythian oracle at Delphi.

The Senate set about considering how the goddess might be transported to Rome. There was then no alliance with the states of Asia. But King Attalus was on friendly terms with the Romans because they had a common enemy in Philip II of Macedon. The Senate, therefore, selected an imposing embassy from the noblest Romans. A convoy of five quinqueremes was ordered for them that they might make an appearance suited to the grandeur of the Roman people. The embassy landed on their way and made inquiry of the oracle at Delphi, and were informed that "they would attain what they were in search of by means of King Attalus, and that when they should have carried the goddess to Rome they were to take care that whoever was the best man in the city should perform the rite of hospitality to her." The king received them kindly, but refused their request; whereupon an earthquake tremor shook the place and the goddess herself spoke from her shrine, "It is my will. Rome is a worthy place for any god; delay not." The king yielded; a thousand axes hewed down the sacred pines and a thousand hands built the vessel. The completed and painted ship received the stone and bore it to the mouth of the Tiber.

It was the spring of the following year before the ship arrived. Meanwhile new prodigies frightened the people. A brilliant meteor had crossed Italy from east to west, a little south of Rome, and a heavy detonation followed. From this, or from some other meteor, another shower of stones had fallen. In expiation, according to the custom of the country in case of stonefalls, religious exercises during nine days were ordered. The Senate, after careful deliberation, selected one of the Scipios, deciding that he, of all the good men in the city, was the best, and they deputed him to receive the stone. The whole city went out to meet the goddess. Matrons and daughters, senators and knights, the vestals and the common people all joined the throng. But a drought had reduced the water of the Tiber so that the vessel grounded upon the bar. All the efforts of the men pulling upon the ropes failed to move it. A noble matron who had been slandered stepped forward into the water. Dipping her hands three times into the waves and raising them three times to heaven, she besought the goddess to vindicate her good name if she had been unjustly slandered. She laid hold of the rope, and the vessel followed her slightest movement amid the plaudits of the multitude.

Scipio, as he had been ordered by the Senate, waded out into the water, received the stone from the priests, carried it to the land and delivered it to the principal matrons of the city, a band of whom were in waiting to receive it. They, relieving each other in succession and handing it from one set to another, carried it to the gates of the city and thence through the streets to the temple of Victory on the Palatine Hill. Censers were placed at the doors of the houses wherever the procession passed, and incense was burned in them, all praying that the goddess would enter the city with good will and a favorable disposition. The people in crowds carried presents to the temple. A religious feast and an eight days' festival with games were established to be celebrated thereafter each year in the early part of April.

Before another year had passed, Hannibal, after having maintained his army in Italy for fifteen years, was forced to withdraw again to Africa. From the liberal offerings of the people, in gratitude for deliverance, a temple was erected to Cybele, long known as the Temple of the Great Mother of the Gods, so that twelve years after its arrival at Rome the stone was taken from the Temple of Victory and set up in its new home. A silver statue of the goddess was constructed, to which the stone was made to serve in place of a head. Here, in public view, for at least five hundred years that stone was a prominent object of Roman worship. Its physical appearance is described by several writers. It was conical in shape, ending in a point, this shape giving occasion to the name Needle of Cybele. It was brown in color and looked like a piece of lava. Arnobius, a Christian writer just before the accession of Constantine, and over five hundred years from the date of its arrival at Rome, says of the stone:

"If historians speak the truth and insert no false accounts into their records, there was brought from Phrygia, sent by King Attalus, nothing else in fact than a kind of stone, not a large one, one that could be carried in a man's hand without strain, in color tawny and black, having prominent, irregular, angular points, a stone which we all see to-day, having a rough irregular place as the sign of a mouth and having no prominence corresponding to the face of an image." Arnobius goes on to ask whether it was possible that this stone drove the strong enemy Hannibal out of Italy—made him who shook the Roman state unlike himself, a craven and a coward.

Just when this stone disappeared from public view I do not know. In directing the recent excavations on the Palatine Hill, Prof. Lanciani was at first in great hopes of finding it; because it had no intrinsic value to the many spoliators of Rome nor to the former excavators of Roman temples. But the place in which he expected to find it was absolutely empty. At a later date, however, he found in a rare volume an account of excavations made on the Palatine Hill in 1730, in which the private chapel of the Empress was found and explored. In this we perhaps have an account, and, it is to be feared, the last account of a sight of the Cybele stone. The writer says: "I am sorry that no fragment of a statue, or bass relief, or inscription has been found in the chapel, because this absence of any positive indication prevents us from ascertaining the name of the divinity to whom the place was principally dedicated. The only object which I discovered in it was a stone nearly three feet high, conical in shape, of a deep brown color, looking very much like a piece of lava and ending in a sharp point. No attention was paid to it, and I know not what became of it." This description is almost identical with that given by Arnobius and others of the stone from Pessinus.

Another stone of meteoric origin was brought to Rome, and there for a brief period was most fantastically worshiped. This was near the beginning of the third century after Christ. It came, like the other stones of which I have spoken, from Asia. In the city of Emesa, on the banks of the Orontes, about midway between Damascus and Antioch, there was in those days a magnificent temple of the sun. A gorgeous worship was maintained before a stone that fell from heaven that served as the image of the sun god. The description of the stone is not very unlike that of the Cybele meteorite. Herodian, who probably saw it, says: "It is a large stone, rounded on the base, and gradually tapering upward to a sharp point; it is shaped like a cone. Its color is black, and there is a sacred tradition that it fell from heaven. They show certain small prominences and depressions in the stone, and those who see them persuade their eyes that they are seeing an image of the sun not made by hands."

This sun god was named Heliogabalus, and before the altar a boy of nine years of age began to serve as priest. Such a Syrian service did not make the boy grow manly nor virtuous, and when at the age of fifteen he became emperor through the money and intrigues of his grandmother, and the murder of the Emperor Macrinus, we have for three years at Rome the view of the sorriest scapegrace that ever sat on a throne. He assumed with the name of Antoninus also the name of his god Heliogabalus. To the great disgust of the Roman Senate and people, he brought with him from Syria the image of his god, the sacred stone, and himself continued before it his priestly service with all its fantastic forms and gesticulations. He built within the city walls a grand and beautiful temple, with a great number of altars around it; he repaired thither every morning, and sacrificed hecatombs of bulls and an infinite number of sheep, loading the altars with aromatics, and pouring out firkins of the oldest and richest wines. He himself led the choruses, and women of his own country danced with him in circles around the altars, while the whole senatorian and equestrian orders stood in a ring like the audience of a theater.

But now he must have a wife for his god. So he broke into the apartments guarded by the vestals and carried to the palace the Trojan Palladium, or what he supposed was that object, and was intending to celebrate the nuptials of the two images. His god, however, he concluded, would not be pleased with a warlike wife like Pallas; therefore, he ordered to be brought from Carthage an ancient image of Urania, or the moon, which had been set up by Dido when she first built old Carthage. With this image he demanded the immense treasures in her temple, and he also collected from every direction immense sums of money to furnish to the moon a suitable marriage portion when married to the sun.

He built another temple in the suburbs of Rome, to which the Emesa stone, the god (?) was carried in procession every year, while the populace were entertained with games, and shows, and feastings and carousings. Herodian thus describes this performance:

"The god was brought from the city to this place in a chariot glittering with gold and precious stones, and drawn by six large white horses without the least spot, superbly harnessed with gold, and other curious trappings, reflecting a variety of colors. Antoninus himself held the reins—nor was any mortal permitted to be in the chariot; but all kept attendant around him as charioteer to the deity, while he ran backward, leading the horses, with his face to the chariot, that he might have a constant view of his god. In this manner he performed the whole procession, running backward with the reins in his hands, and always keeping his eyes on the god, and that he might not stumble or slip (as he could not see where he went), the whole way was strewn with golden sand, and his guards ran with him and supported him on either side. The people attended the solemnity, running on each side of the way with tapers and flambeaux, and throwing down garlands and flowers as they passed. All the effigies of the other gods, the most costly ornaments and gifts of the temples, and the brilliant arms and ensigns of the imperial dignity, with all the rich furniture of the palace, helped to grace the procession. The horse and all the rest of the army marched in pomp before and after the chariot."

The reign of a foolish boy at this period of Rome's history was necessarily a short one, and at the age of eighteen the soldiers killed him and let the Roman populace have the body to drag through the city streets. The worship of the sun god at once ceased, and, no doubt, the stone also was thrown away. The Cybele stone, however, remained an object of public worship, since the quotation from Arnobius, which I have given, was written nearly a century later than the reign of Heliogabalus.

I propose to speak briefly of one more meteorite whose worship has had a world-wide fame: the image of the Ephesian Artemis. This worship had its center at Ephesus, but was widely extended along the shores of the Mediterranean. Temple after temple was built on the same site at Ephesus, each superior to the preceding, until the structure was reckoned one of the seven wonders of the world. As a temple, it became the theater of a most elaborate religious ceremonial. As an asylum, it protected from pursuit and arrest all kinds of fugitives from justice or vengeance. As a museum, it possessed some of the finest products of Greek art, notably works of Phidias and Apelles. As a bank, it received and guarded the treasures which merchants and princes from all lands brought for safe keeping. In its own right it possessed extensive lands and large revenues. The great city of Ephesus assumed as her leading title that of *νεωκόρος*, or temple-warden of Artemis, putting her name on her coins and in her monumental inscriptions.

The image, which was the central object in this temple, was said to have fallen from heaven. Copies of it in all sizes and forms were made of gold, of silver, of bronze, of stone, and of wood, by Ephesian artificers, and were supplied by them to markets in all lands. What a lifelike picture is given us, in the nineteenth chapter of the Acts of the Apostles, of the excited crowd of Ephesians, urged on by the silversmiths, who made for sale the silver shrines of the goddess, and who saw that their craft was in danger if men learned to regard Artemis as no real divinity, and to despise the image that fell down from the sky!

We cannot suppose that the Ephesian Artemis image of the first century was a meteorite, though we have the distinct appellation, Diopetes, fallen from the sky. But I believe that there was a meteoric stone that was the original of the Ephesian images, and it seems not at all improbable that in some one of the destructions of the temple it disappeared. Or, in the progress of time, there may have been a desire to represent the goddess in a more artistic form than the shapeless stone afforded.

Many forms of the Ephesian Artemis are still preserved, and they have, amid all their variations, a certain peculiar character in common. That common character seems to me to confirm the statement that the original image fell from heaven. This goddess is

regarded, let me say, as different from the Grecian Artemis, the beautiful huntress so well known in Greek art, and I am speaking only of the images of the Ephesian Artemis.

There is one peculiarity in the outward forms of the meteorites that is characteristic of nearly all of them. I mean the moulded forms, and the depressions all over the surfaces. They are better appreciated by being seen than by any description I can give you. They are common to meteorites of all kinds, from the most friable stone to the most compact iron. (I show you one, a stone from Iowa—also the plaster cast of another, a stone from some fall, I know not which one.) Those who have lately visited the collection in the Peabody Museum may recollect the model of an iron that fell two or three years ago in Arkansas, which displays most beautifully these depressions.

Let now an artist attempt to idealize any one of these moulded forms, and to make something like a human shape out of one of them. He must necessarily set it upright, and he must give it a head. You have then a head surmounting one of these moulded forms. Let now the convenience and the taste of the artificers of the images have some liberty to act—and we know that they did act, for we have considerable variety in these images—and a development in the conventional representation of the image is sure to follow.

THE KALAMAZOO CARRYCYCLE.

THERE are many people in the world who, on account of ill health, deformity or feebleness, cannot find comfortable means for moving about out of doors. They cannot stand the jolting of a carriage, and, frequently, cannot get in and out of one. The push chairs which are in general use answer quite well, but they can only be moved at a slow rate; they are hard to push, and are not as easy and as comfortable to ride in as might be expected. The vehicle which we illustrate is intended to do away with these objections. The invalid sits in a willow chair and rides along on pneumatic tires close to the ground, with nothing in front to obstruct the view. The vehicle is propelled at a quick or slow pace, as desired, by a person having perfect control of the machine, who can run it anywhere to suit the invalid.

As all the revoluble parts are fitted with ball bearings the friction is reduced to a minimum. The carrycycle has a frame constructed with a drop or low upper bar, so that either a lady or gentleman can ride to propel the machine. As in a vehicle of this kind speed is not much desired, the gear is only 45, 50 or 56, and with a low gear the carrycycle propels very easily. On a steep incline the operator can walk and push the machine with the person in the chair much easier than most push chairs can be pushed. By riding behind, the operator has the occupant of the chair constantly in view, which is decidedly the safest and best position, while the invalid or person in the chair has a clear view in front, which is much pleasanter than riding behind the operator, where the view would be obstructed and every exertion of the operator in plain view of invalid. Again, by having the chair in front the chair can sit close to the ground and tilt forward, so that in order to get into it, all any one has to do is to back up to it and sit down. The operator then brings the chair backward to its normal position and secures it by means of a link or hook. The chair rests on flat U-shaped steel springs, one on each axle, and these springs rest on the front axle of the carrycycle in a manner to allow them to pivot when the chair is tilted.

The steering gear is probably the most interesting feature of the vehicle. The cross bars are coupled at their forward ends by ball bearing heads to the front axle, while the rear ends of the cross bars are coupled by ball bearing heads to the rear frame. The tendency of these cross bars, when pushed together, is to cause the machine to go ahead in a straight line. This makes the machine much easier to steer than can be done by any other method. It also allows the machine to be made much more compact, both as regards width and length, than can be made in other ways. By this construction the front wheel, which carries the load, will

THE KALAMAZOO CARRYCYCLE.

yield while passing over obstructions, thereby making it easier for the load or person riding in the chair than it could possibly with a rigid, unyielding axle for the wheels carrying the load. The carrycycle is also provided with a box or cabinet attachment.

We are indebted to the Kalamazoo Cycle Company for the illustrations and particulars for this article.

MILL SET IN MOTION BY AN OX OR HORSE.

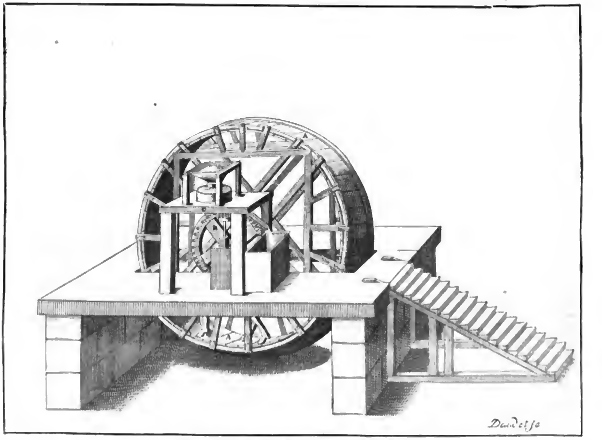
AFTER the large wheel, A, and the rest of the machine shown in the figure has been strongly constructed, an ox that has been previously taught to walk in the wheel is led into it. When the ox effects the motions necessary for walking, he does not change place, but makes the wheel do so; or, to be more explicit, at the part of the circumference upon which his feet rest, he cannot, by reason of the proportion that exists between his weight and the stress necessary to give motion to the mill, move from the line perpendicular to the axis of the wheel in which he is inclosed without causing the latter to revolve.

Thus, the animal, in continuing to revolve the large wheel, A, in this manner, allows the latter to communicate its motion to the face wheel, B, which is at the end of its axle, and consequently to the lantern wheel, C, and the mill stone.—Recueil d'Ouvrages Curieux de Mathematique et de Mecanique, 1733.

AMERICAN MADE MACHINE TOOLS.

ONE of the most important outcomes of the present dispute in the engineering trade will be, it is generally admitted, the development of machine tools in this country. We believe that already not a few firms have under contemplation the design and erection of automatic machinery for doing work which is now done mainly by hand. The anticipated result is that, in place of the arrangement which now very generally obtains of one workman, one tool, one man will, as in America, be able to attend to several tools at once. The innovation will, of course, be opposed tooth and nail by the trades unions, if there is any fight left in them. They have insisted on the one man, one job arrangement, and as they have had the power to enforce, or the masters have had the complacency to grant the demand, few attempts have been made in this country to bring the automatic tool to anything like the perfection that it has attained in the United States notably, and in Germany to a rather less degree. There can be absolutely no question as to the ability of our mechanicians to invent and make the machines as soon as the restrictions on their use are removed. Let anyone who doubts it consider for a moment the automatic machinery of other classes whose birthplace has been in England. Consider only the wonderful machinery of our cotton mills or of our printing establishments. Could not the engineers who have created and designed such highly automatic machinery as this produce, if necessary, tools which as a rule present far less complicated problems? It is unquestionably true that there are in this country hand worked factories into which mechanical methods, one would imagine, might be introduced with advantage. The manufacture of steel pens may be instanced. At Birmingham the work is almost entirely done by girls and old pattern screw stamping presses. It has been stated that this class of work cannot be done automatically. The statement is hardly credible. The fact is in all likelihood that the effect of throwing a large number of persons out of employment is contemplated with dislike. The existence, therefore, of a few cases of this kind in no degree disproves the ability of the Englishman to invent the machinery required.

The use of the machine tool in America is entirely unrestricted. The development of it has, therefore, made great strides. The importation of American tools into this country need not, however, be regarded with the slightest uneasiness. We have not the least hesitation in saying that many English firms can and will produce tools as good as those now being imported. The American tool is not entirely adapted to English work, and in certain respects is distasteful to the British workman. It would not be easy to say why in all cases. The matter is one of taste, just as a Scotchman blows his bagpipes with his mouth while an Irishman blows his with his elbow. Equally attractive music is to be got out of both, but heredity prejudices each nation in favor of a particular type. In other cases it is perfectly easy to account for the Englishman's dislike. One or two of these reasons we may point out. A noticeable feature of American tools is the shortness of crank handles or their replacement by little wheels. We do not question that the American arrangement is designed to give the same power approximately as the English device. To the English mind, however, it does not give the same sense of power and security. Moreover, the control is unquestionably less complete, and the labor is rather increased if any



MILL SET IN MOTION BY AN OX OR HORSE.

thing. Not long ago we saw a large American lathe by a well known firm at work. It was in many respects an excellent tool. The foreman in charge of it said he believed it was a good machine, but nevertheless he did not like it, and never felt quite at home with it. One of his chief objections was that whereas he was accustomed to a long rack handle always well within reach of hand or toe, and having a good, steady working leverage, the tool under discussion had quite a short counterbalanced handle, and not only needed many rotations to run the slide rest back, but, as we have said, left the operator without the sense of the power of controlling his machine. There are other points, too, which a cursory examination reveals. The most potent is the use of a simple instead of a compound rest on lathes fitted with taper gear. Practically all English lathes have two hand screws on the rest, giving motions normally at right angles, one parallel with and the other perpendicular to the lathe centers. The American, however, uses the latter only. Now in English shops the former gear is used universally for adjusting the cut when facing, and the absence of it is consequently embarrassing. The American does the same thing by clamping down the lead nut and turning the leading screw by hand. We do not doubt that very good work can be done in this way—our cousins are excellent mechanics—but it does not strike one as being so convenient as the method to which we are accustomed, and from which we shall not depart readily. Other points in which American and English practices differ will occur to users and makers of machine tools. We think most of our readers will agree with us that the Englishman prefers an English made tool.

We are none the less perfectly ready to admit that American tools are in many respects ingeniously devised and excellently constructed. Makers in this country have much to learn from them; that they will learn much and turn their knowledge to good account we do not doubt for a moment. In making his designs the Englishman will find that the American practice is unsuitable in several respects. It must not be forgotten that American cast iron is a far softer material than ours. Higher speeds and greater feeds can, in consequence, be used than are ever employed here. The very same fact renders alteration in the design of the main castings of a machine necessary. Besides these vital points there are less important details which need observance if outrage is not to be done to the conservatism of English engineers and mechanics. On the whole, therefore, a slavish copy of American tools is as little likely to make much progress in this country as the original tools themselves. We want automatic machine tools, but we want them stamped with our own and not American characteristics.—London Engineer.

NEW GASOLINE MOTORS.

AT the Hungarian Millenary Exposition held recently at Budapest, Messrs. Ganz & Company exhibited some interesting gas motors that are worthy of notice. These motors are of the Banki & Csonk type, with distribution by valves. Those of two horse power especially are now largely used in agricultural exploitations for cutting straw, slicing beets, grinding wheat, churning, etc. They are usually coupled with a pump for raising water.

The gasoline engine represented in Fig. 1 is of the two horse power type. The gasoline reservoir is placed upon the motor and the cooling of the water is effected by means of a fan mounted upon the side of a large iron plate box that carries, in addition, a small centrifugal pump keyed upon the same axle. The suction pipe of this pump descends to the bottom of the box, while the force pipe is connected with the jacket of the cylinder. The forcing of the water, which is heated in contact with the cylinder jacket, is effected through a pipe that starts from the upper part of the box, where it is provided with a rose that divides the water and allows it to fall back in a fine shower. The draught is produced by the fan in an opposite direction and cools the water, which collects at the lower part of the box, whence it is sent anew around the cylinder. It is always the same water that circulates. It is necessary, however, to make additions to it in order to compensate for losses due to evaporation.

The engine that we represent in Fig. 2 is provided with two ten horse power cylinders that actuate a large centrifugal pump. The gasoline reservoir is placed upon the roof of the vehicle, and the cooling is effected directly by means of the pump, the force and suction pipe of which are connected respectively through branches with the cylinder jacket and cover. A small reservoir serves to effect such cooling when the motor is running without the pump.

In the locomotive engines, which operate in most cases in the open air, the suppression of an external flame for ignition is advantageous in every respect.—Revue Industrielle.

TWO HORSE POWER GASOLINE MOTOR.

TEN HORSE POWER GASOLINE MOTOR COUPLED WITH A CENTRIFUGAL PUMP.

PADDLE ENGINES WITH JOY GEAR.

WE publish an engraving of a set of paddle engines constructed by Messrs. Alley & Maclellan, of Sentinel Works, Polmadie Road, Glasgow. These engines, which are noticeable from being fitted with Joy valve gear, are of the triple expansion jet condensing type, and have cylinders 18½ in., 28½ in. and 45 in. in diameter respectively, with 48 in. stroke. They are designed to indicate 600 horse power at 50 revolutions per minute, with a boiler pressure of 150 lb. per square inch.

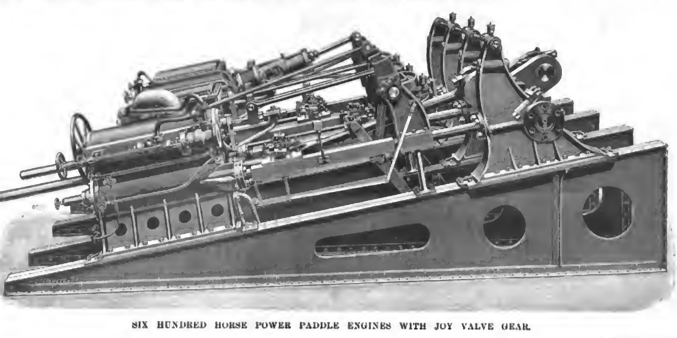
The crankshaft is built of Siemens-Martin steel, and is fitted with Alley's patent flexible coupling. The paddle wheels are of the usual feathering type.

The valve gear is of the Joy radial type, the reversing gear being arranged with steam and hydraulic cylinders worked by a handwheel from the back of the cylinders, arranged in such a manner that combined steam and hand gear, or steam gear only, or hand gear only, can be utilized for reversing purposes.

All the pumps are auxiliary, the feed and bilge pumps being of the duplex type. The air pump is a drum pump driven by a tandem compound engine.

The engines are designed for light draught steamers, the engine frames being built up of steel plates and solid double angle frames, for the purpose of stiffening the hull.—Engineering.

The difference between rising every morning at six and at eight in the course of 40 years amounts to 29,200 hours, or 8 years 121 days and 16 hours, which are equal to eight hours a day for exactly ten years, so that rising at six will be the same as if ten years of life were added.



SIX HUNDRED HORSE POWER PADDLE ENGINES WITH JOY VALVE GEAR.

THE BRIDGES-LEE PHOTO-THEODOLITE.

The idea of using the camera as a surveying instrument has occurred independently to quite a number of engineers, though apparently the honor of being the pioneer in the matter must be conceded to Colonel Laussedat, of the French army. The credit of introducing the system on an extensive scale for the production of topographic plans must, however, be awarded to Mr. E. Deville, the surveyor-general of Dominion lands, who has introduced the method very extensively into his department; no less than 14,000 square miles of territory being thus surveyed during 1893 and 1894, in connection with the settlement of the international boundary between Canada and Alaska. Since then the method has been adopted more or less extensively in the United States, and in its own special department seems likely to oust all rivals. One great advantage of the camera as a surveying instrument lies in the fact that it is much less dependent on the weather than is a plane table, this latter being the particular instrument with which it more especially compares. With the plane table all work must be done in the field, while with the camera, the whole of the plotting being done in the office, the wet and dull days of winter can be used to work up the photographs taken during the finer summer weather. In the Rocky Mountains, Mr. Deville states, plane table work costs at least three times as much as a camera survey. Moreover, with the latter it is possible to make first a rough plot showing only the more prominent features of the ground, and then, if later on a more detailed plan is required, this can be made from the original photographs without necessitating a fresh visit to the ground. As with the plane table, any required degree of accuracy can be obtained by multiplying the photographs taken.

The principle on which the method is based rests upon the geometric truth that if the bearing of any individual object on a photograph from the camera station is known, then the bearing of every other point shown on the print can be calculated, if the focal length of the lens is known. Two photographs being taken of the same landscape from two different stations, and the distance and relative bearing of these two being known, then the whole landscape can be plotted by means of intersections, just as in plane tabling, but with the photographic method the whole of the work can be done at ease in the office.

Special cameras have been devised to simplify the work, the essentials being a method of marking on the negative a vertical and a horizontal line intersecting on the axis of the lens. The bearing of the optic axis may be obtained from a compass, and noted at the time the exposure is made. A more convenient method has, however, been devised by Mr. Bridges-Lee, of 6 King's Bench Walk, E. C., who places a compass, having its divisions engraved on a vertical ring of transparent celluloid, inside the camera in such a position that the bearing of the optic axis is automatically recorded on the plate at the same time the exposure is made. A camera thus constructed was described in our issue of July 31, 1896. More recently Mr. Bridges-Lee has made further additions to the instrument, which, as made by Mr. L. Casella, of 147 Holborn Bars, E. C., now takes the form shown in our engraving. The body of the camera is of aluminum, and fits on to a theodolite base below, while at the top is a telescope, small, but of excellent quality, which enables the instrument to be used as an ordinary theodolite when desired, large vertical angles being observed when necessary by a prism or mirror attachment. The divided horizontal circle enables azimuth readings to be made to half a minute of arc, a vernier and reading microscope being fitted as shown. The latter is carried on a telescopic arm and can also be used for reading the compass bearing through a window in the focusing screen. The level shown at the top of the camera moves on a circular run, and enables the instrument to be leveled without necessitating the turning of the camera as a whole. Inside the camera is a frame sliding on ways, and carrying in the first place the compass already mentioned; and, secondly, the cross wires, which by their shadows mark on the negative the principal vertical and horizontal lines of the picture. When a slide is in place and the shutter withdrawn, the frame already mentioned is moved up by the milled head shown to the right of the camera, until its edges are in contact with the sensitive plate. The latter is then carried back with the frame until further motion of the latter is arrested by fixed stops, so that, whatever the thickness of the plate, the distance of the sensitive surface from the lens is always the same. The cross strip shown attached to the back of the frame is of glass, and carries an accurate tangent scale, which enables the horizontal angle which any object shown on the print makes with the optic axis to be determined directly by the use of a parallel ruler or a pair of dividers. The two little strips of celluloid shown below and at either end of the tangent scale are removable, and on them can be written previous to taking the photograph such data as the camera station, its number and elevation, date, etc., all of which will then be reproduced on the negative, and thus any possible danger of confusing two negatives on the subsequent plotting is totally avoided. The information recorded on a negative in this way is shown in Fig. 2, which is reproduced on the sky of each negative. The lens adopted is of the rectilinear type, and is used with a fixed focus and a very small stop. In order to avoid photographic haze, which tends to render distant objects indistinct, isochromatic plates and a yellow or green screen are made use of, and with this precaution there is no difficulty in getting sharpness in the "distance" of the picture.

To secure the stability of the instrument during the long exposure entailed by the use of this screen and the small lens aperture adopted, it is usual in Canada to carry a net, which is hung on the camera tripod when set up and filled with stones, the precaution being taken of letting the bottom of the net just scrape the ground, as otherwise it would swing with the wind and cause shaking.

Having obtained a plan of a survey in the way described, the introduction of contour lines is not difficult, since the distance of any particular point from the camera station is then known, and its depth above or below the horizon line in the print is a measure of its angular elevation or depression as observed from the camera station. The level of a few points being thus ascertained, the contours can be filled with considerable accuracy by estimation from the appearance of the photograph.—Engineering.

THE BRIDGES-LEE PHOTO-THEODOLITE.

LABELS FOR DRY PLATES.

Probably a considerable number of readers will now be planning their Continental trip, and there will be even among the oldest travelers a certain amount of fear—"Shall I get my plates through safely?" Especially will this be so if one's vocabulary is bounded by the "Have you the pens, ink, and paper?" limitations, which with the aid of native hospitality may be sufficient to provide the necessaries of life when once we are in the country itself, but will scarcely enable us to explain the contents of that mysterious parcel of plates or films to the Custom House officials. The best way then is to have a few labels printed and gummed so that they may be stuck on to each package of sensitive material, and which, with the truthful expression which the photographer always wears, *will* satisfy the officers that no dynamite, or tobacco, or matches, or tea, or India rubber soled boots are being smuggled in. Here is a list of the inscriptions for the various countries:

ON GAMBIER-FLUORESCIN AND GAMBIER-CATECHU RED.

By Karl Dieterich.

The author has stated before that gambier-catechu, in contradistinction to pegu-catechu, contains a fluorescent body whose character he now describes more closely. The same is called gambier-fluorescin and is of a highly decomposable nature, for which reason it could not be obtained isolated pure, but only in solution. It is a basic body, which passes into a red resin by oxidation in the air, which Dieterich names gambier-catechu red. The gambier-fluorescin is not con-

tained in a free stale in the catechu, but is apparently combined with catechine and catechu tannic acid, in the same way as ester. By carbonic or caustic alkalies, however, it is readily split off and can then be shaken out with benzine or ether, besides two other bodies of an oil like and waxlike nature. The gambier-catechu red is not similar to pegu-catechu red already known. It melts at 130–131° C., is almost insoluble in ether, and is no longer, like the fluorescin, of purely basic character. It can be acetylized and has a percentage of acid of 95·2, while the ester number was 30. Owing to the fact that only 1 gramme of catechu red could be obtained from 5 kilogrammes of gambier, the investigation has not very far advanced.

The fat oil above mentioned contained 14·89 per cent. of acid and 43·33 per cent. of ester, while the percentage of iodine is exceedingly small. The small quantity of this substance, as well as of the wax also present in catechu, makes a more accurate examination impossible for the time being.—Ber. Pharm. Ges.

THE CHIME AT ST. GERMAIN L'AUXERROIS.

FORMERLY, when church chimes were rung by hand, it was always effected by maneuvering the clappers inside the bells by the aid of pedals and of keys arranged on a sort of keyboard.

The old automatic system consisted of a metallic cylinder covered with numerous projecting pins, and rotated by a clockwork movement. In revolving, this cylinder raised, by means of the pins on its surface, the levers, which were connected by wires with the clappers; and the latter, on falling back against the bells, produced the tones necessary to play the desired airs.

When it was desired to obtain very powerful tones and to play tones of some length, an enormous power had to be expended. By the aid of the keyboard and its attachments it was necessary, in fact, to raise clappers, which in some cases were extremely heavy, and to overcome a resistance that could be surmounted only by great trouble, and that too by striking with the fists on the keys and with the feet on the pedals. (Fig. 1.) When the automatic cylinder was employed, it was necessary (owing to the fact that it had to raise heavy clappers) to give it dimensions varying from 3½ to 6½ feet in diameter, and a very considerable rotary power. To actuate these machines, weights of from 1,000 to 6,000 pounds were employed. These were suspended from chains rolling around drums, and were wound up by means of windlasses, requiring the labor of from one to three men for one or two hours. The chime of the Samaritaine, at Paris (destroyed in 1813), was on this system. At Bruges, Belgium, there is a very perfect chime of the same kind. It is provided with a bronze cylinder weighing no less than 22,000 pounds, and representing a value of $8,000 for the metal alone. These old fashioned chimes, as may well be seen, were very costly and inconvenient. They utilized at the very most only 30 per cent., or at the least one third of the force expended. This will be readily understood if it be taken into consideration tha[illegible]r, always revolving with the same spe[illegible] much power to sound a 6 pound bel[illegible] large one weighing 6,000 pounds.

T[illegible]e tower of Saint Germain l'Auxerrois, at [illegible] essentially from those above described [illegible]s a great progress in the manufacture [illegible]aratus. It consists essentially of: (1) sets of wheels and weights equal in number to that of the bells and of power porportionate to the weight of the latter; (2) of a keyboard similar to that of a piano and operated the same way; (3) of a cylinder for playing automatically, of about 16 inches diameter, so arranged that it can be removed and replaced by others affording other tunes. The importance of the revolution effected in the mechanism may be realized when we state that this chime, instead of needing the labor of two or three men during a part of a day for winding it up, requires but the labor of one man for ten minutes each week to wind up the weights connected with the automatic part, which is arranged to play four airs per day. Fig. 2 shows the chime as now definitely located in the tower of St. Germain l'Auxerrois.

In the old system of chimes there was but one mechanism for all the bells, but in this each bell has a special set of motive wheels of a power proportioned to the weights. As each set of wheels can operate only when it is desired to obtain the sound of the bell connected with it, it uses its power only when it acts. The manufacturer has based his calculations of the motive weights on data from experiments, which have shown that, in large bells giving the bass tones in the chimes, the effort necessary to raise the clappers is about equal to a hundredth of the weight of the bells; a bell of 4,000 pounds, for example, requiring an effort of 40 pounds. But in the small bells the effort is relatively greater in proportion to their weight, and may be estimated at about one-fifth; so that for a bell of 20 pounds, for instance, an effort of 4 pounds would be necessary. As may be seen, then, this division of the weights and sets of wheels affords considerable economy in motive power. This arrangement, moreover, has the advantage that the wheels operate with sufficient speed to allow passages to be readily played which contain quavers and semiquavers.

Finally, it may be remarked that one of the characteristic features of this chime is that the operations of the automatic cylinder are effected without any outside aid—the mechanism once wound up taking care of itself.

DETECTION OF TAR DYESTUFFS IN CLARET.

SULPHIDE of zinc forms a very stable lake with the dyestuff of wine, of bilberries, mallows, as well as with archil, litmus and cochineal, while tar dyestuffs can be very easily abstracted from the mixture with alcohol or water. This behavior of the sulphide of zinc forms the basis of a new method of isolating tar dyestuffs from claret. Not every sulphide of zinc can be used. Most advantageous was found the preparation which is obtained from a chloride of zinc solution mixed with ammonia in excess by precipitation with a sufficient volume of sulphide of hydrogen. The precipitate is washed until free from chlorine and dried at a temperature kept below 35° Cent. To test claret for tar dyestuffs, grind five grammes of sulphide of zinc in enough wine so that a scarcely liquid mixture ensues, then add a little water until the mixture is fluid; allow to deposit, filter and abstract. In case the fluid appears colored, elute the dyestuff by washing with water. The colored filtrate is evaporated, the residue extracted with 90 per cent. alcohol, and the filtered solution once more evaporated to dryness. The dyestuff can now be dissolved with alcohol and used for identity reactions. If the dyestuff of the sulphide of zinc-wine mixture does not pass into the water, treat the filter residue again moist with the same volume of 90 per cent. alcohol, heat moderately while stirring, filter and abstract the dyestuff by washing with alcohol. Indigo carmine, which can be isolated by means of water, behaves in the same manner as tar dyestuffs. Alcohol, however, easily abstracts them if they are soluble in it. Otherwise a like volume of alcohol is poured over the moist precipitate in a porcelain dish, in such a manner that the mixture does not wet the walls above it of the vessel. If the liquid is evaporated without stirring, dissociation of the lake will set in and the dyestuff will adhere to the wall of the dish. The evaporation is continued to dryness, the sulphide of zinc removed from the dish and the dyestuff dissolved with water. This abnormal behavior was observed only with three blue tar dyestuffs. According to the described method it can be readily ascertained whether fuchsine or a sulphur acid is present, as the latter is already soluble in water; fuchsine, however, only in alcohol. For the identification of the different dyestuffs the author has compiled an extensive table.—Chemiker Zeitung, from Rev. Chim. Anal. Appliq., 1897, 5, 62.

METHOD OF PRODUCING INCANDESCENT MANTLES.

SUCH a mantle is obtained, as has been shown by the incandescent light patent suits (Chem. Ind.), by saturating the knit cotton hose with a 30 per cent. solution of the nitrates of thorium and cerium (99 : 1), drying in the air and incinerating. The ashes at first are entirely soft and flexible; by annealing by means of suitably shaped pressed gas burners the substance is caused to slag and harden, and at the same time it is given the bell-like shape. Now the mantle is hung up, by means of an asbestos thread drawn through its head, upon a magnesia pencil in the middle of the burner (commonly iron pencils were used). To take the place of the magnesia pencils, of late pencils of fire clay have been introduced in the market; as the former, being made of finely ground magnesite and exposed to strong white heat, frequently slake in damp air and consequently quickly crumble into dust. The highest illuminating power of the mantles is dependent on the proportion of aluminum 99 and cerium earth 1. An increase of the percentage of cerium changes the white light of that mixture more and more into yellow; pure nitrate of thorium is luminous in the Bunsen flame only with a dead, red-violet, pale light; likewise nitrate of cerium alone or mixed with up to 70 per cent. thorium only gives off a dark, blood-red to orange-red light. Important is the production of pure salts of thorium and cerium, which are at present prepared from the monazites. The separation of cerium from didymium and lanthanum is considered particularly difficult, and for this purpose Mozander's process, modified by O. N. Witt, is recommended. The raw dioxide of cerium thus obtained is dissolved in nitric acid, nitrite of ammonium added, and the nitrate of ceriammonium is allowed to crystallize out. These orange-red crystals, reduced in an aqueous solution with alcohol and evaporated, yield the beautifully crystallizing ceriammonium used in mantles as nitrate of cerium.

Rhinometers are devices to measure the amount of air a man breathes through his nose, in order that his doctor may compare it to the amount he should take in that way.

SELECTED FORMULÆ.

Soldering Aluminum.—Another new solder for aluminum has been brought out in the United States under the title of Green's aluminum solder. It is stated to be composed of zinc, 59·03 per cent.; tin, 47·99; aluminum, 1·76; and phosphorus, 0·22 per cent. It is not used with any flux, simply requiring the aluminum faces to be cleaned and coated with the solder, then a clean hot bit is used to wipe the joint to be made.

Tanning Hides for Robes.—The hides should be very thoroughly soaked in order to get a complete softening. For dry hides this will require a longer time than for salted. A heavy hide requires longer soaking than a skin. Thus, it is impossible, says Hide and Leather, to fix a certain length of time. After soaking, the hide is fleshed clean, and is now ready to go into the tan liquor, which is made up as follows: One part alum, 1 part salt, ½ to ¼ part japonica. These are dissolved in hot water in sufficient quantity to make a 35° liquor. The hide, according to the thickness, is left in the tan from five to ten days. Skins are finished in about two or three days. The hide should be run in a drum for about two hours before going into tan, and again after that process. In tanning hides for robes, shaving them down is a main requisite for success, as it is impossible to get soft leather otherwise. After shaving put back into the tan liquor again for a day or two and hang up to dry. When good and hard, shave again and lay away in moist sawdust and give a heavy coat of oil. When dry, apply a solution of soft soap; roll up and lay away in moist sawdust again. Now run the hides on a drum or wheel until thoroughly soft. The composition of the tan liquor may be changed considerably. If the brownish tinge of the japonica be objectionable, that article may be left out entirely. The japonica has the effect of making the robe more able to resist water, as the alum and salt alone are readily soaked out by rain.—Shoe and Leather Facts.

Spots on Cigars.—The speckled appearance of certain wrappers is due to the work of a species of fungus that attacks the growing tobacco. In a certain district of Sumatra, which produces an exceptionally fine tobacco for wrappers, the leaves of the plant are commonly speckled in this way. Several patents have been obtained for methods of spotting tobacco leaves artificially. A St. Louis firm uses a solution composed of:

Sodium carbonate	3 parts.
Calx chlorinata	1 "
Hot water	8 "

Dissolve the washing soda in the hot water, add the chlorinated lime and heat the mixture to the boiling temperature for three minutes. When cool, decant into earthenware or stoneware jugs, cork tightly and keep in a cool place. The corks of jugs not intended for immediate use should be covered with a piece of bladder or strong parchment paper, and tightly tied down to prevent the escape of gas, and consequent weakening of the bleaching powder of the fluid. The prepared liquid is sprinkled on the tobacco, the latter being then exposed to light and air, when, it is said, the disagreeable odor produced soon disappears.—American Druggist.

Development of Fruit Flavors.—Some very interesting and suggestive results have been obtained by Jacquemin, who finds that by the addition of the leaves of fruit trees, which in themselves have no marked flavor, to saccharine solutions undergoing alcoholic fermentation, a very marked bouquet of the fruit is developed. Thus by immersing pear or apple tree leaves in a 10 or 15 per cent. solution of sugar, and adding a pure yeast, which by itself gave rise to no marked flavor, after fermentation a liquid was obtained which had a strong odor of pear or apple respectively and an excellent flavor, and on distillation gave an alcoholic distillate, in which this aroma was still more marked. Vine leaves act in a similar manner, and the author suggests that it may be possible to improve the bouquet of a poor vintage by the addition of some leaves during fermentation. It is noteworthy that the results are far more marked when the leaves employed are from trees in which the fruit is approaching maturity. The author infers that the flavors of fruits are due to a body elaborated in the leaves, possibly of a glucosidal nature, which is not transferred to the fruits until the latter approach maturity, and is then acted upon by the special ferments contained in the fruit juices and develops distinctive flavors. The matter would appear to be of considerable practical importance.—Pharmaceutical Journal.

An Ever-Ready Pad for Rubber Stamps.—The following is said to be a cushion that will give color permanently. It consists of a box filled with an elastic composition, saturated with a suitable color. The cushion fulfills its purpose for years without being renewed, always contains sufficient moisture, which is drawn from the atmosphere, and continues to act as a color stamp cushion so long as a remnant of the mass or composition remains in the box or receptacle. This cushion or pad is too soft to be self-supporting, but should be held in a low flat pan and have a permanent cloth cover. The composition consists preferably of 1 part gelatine, 1 part water, 6 parts glycerine, and 6 parts coloring matter. A suitable black color can be made from the following materials: 1 part gelatine glue, 3 parts lampblack, aniline black, or a suitable quantity of logwood extract, 10 parts of glycerine, 1 part absolute alcohol, 3 parts water, 1 part Venetian soap, 1·5 part salicylic acid. For red, blue or violet, 1 part gelatine glue, 2 parts aniline of desired color, 1 part absolute alcohol, 10 parts glycerine, 1 part Venetian soap, and 1·5 part salicylic acid. The following are two additional receipts used for this purpose: 1. Mix and dissolve 2 to 4 drachms aniline violet, 15 ounces alcohol, 15 ounces glycerine. The solution is poured on the cushion and rubbed in with a brush. The general method of preparing the pad is to swell the gelatine with cold water, then boil and add the glycerine, etc.

Formaldehyde for Mosquitoes.—Dr. Henry Liston, of Sunderland, states that while on the Zanzibar coast he used a 40 per cent. solution of above for mosquito bites with remarkably quick and good results. It should be applied to the bites as soon as possible with the cork of the bottle, and allowed to dry on.—Western Drug.

THE MANUFACTURE OF ABORIGINAL STONE IMPLEMENTS.

THE origin of a primitive industry is usually shrouded in obscurity, and the narration of the attempts to gather the scattered fragments and build up a picture of early industry is interesting not only to the archæologist, but to the general reader as well. In the Fifteenth Annual Report of the Bureau of Ethnology to the secretary of the Smithsonian Institution, 1893-94, is a most interesting paper on "Stone Implements of the Potomac-Chesapeake Tidewater Province," by William Henry Holmes. Through the courtesy of the director of the Bureau of Ethnology, we are enabled to present a few of the interesting engravings with which the paper is so well illustrated. As the original monograph occupies some 150 pages, all of the details of the explorations will have to be omitted and we shall confine ourselves only to the general conclusions which are adduced.

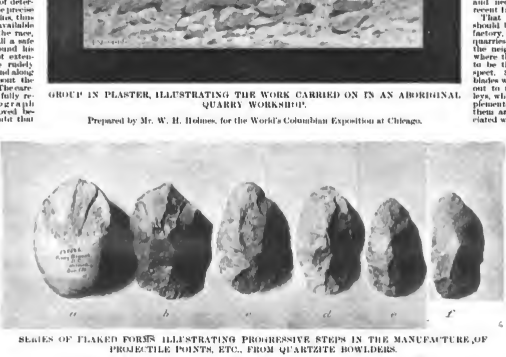
The Indian tribes inhabiting the great province drained by the tidewater tributaries of the Chesapeake were simple fishermen, hunters and warriors, whose art aimed little beyond the supply of pressing needs, and the district now furnishes almost nothing in the way of art remains to attract the popular eye. Little has been preserved beyond the simplest varieties of stone implements; but inconspicuous and elementary as these objects are, they have attracted much attention on the part of archæologists and are now eagerly studied because of their bearing, not only on the history of the region and its people, but on questions of general import in the history of primitive progress. The explorations and studies recorded in the exhaustive paper we have referred to above were for the purpose of determining, if possible, the precise status of these remains, thus making them safely available to the historian of the race, who seeks first of all a safe basis on which to found his structure. The most extensive deposits of the rudely flaked stones were found along the bluffs in and about the city of Washington. The careful investigation so fully recorded in the monograph named above has proved beyond a shadow of doubt that the great deposits are on the sites of workshops connected with extensive quarries where the raw material (cretaceous bowlders) was obtained. It was further found that the widely scattered specimens of the same class were on sites (village sites or otherwise) yielding less plentiful supplies of the available raw material where manufacture had been conducted on a smaller scale. That the vast body of the rudely flaked stones of the province are rejects of manufacture was readily shown.

GROUP IN PLASTER, ILLUSTRATING THE WORK CARRIED ON IN AN ABORIGINAL QUARRY WORKSHOP.

Prepared by Mr. W. H. Holmes, for the World's Columbian Exposition at Chicago.

As a second step in the investigation it was deemed necessary to determine the exact relation of these objects with the real implements of the region. This was accomplished by first determining, by most careful studies of the rejectage of the great flaking shops, just what the product of the flaking operations was. This product, so far as the progress of specialization of form on the shop sites indicates, was found to be a leaf-shaped blade. A third step in these explorations was then undertaken for the purpose of determining the destiny of these blades—where they were carried and how and by whom used. Many specimens of identical form were found on Indian village sites in all parts of the surrounding region and in several cases on sites of historic Algonquian settlements, where they were intimately intermingled with the midden refuse, pottery, and neolithic implements. It was further discovered that a large percentage of the countless stone implements—knives, spearheads, arrowpoints, etc.—found in the broad valley below were of leaf-shaped genesis; that before they received their final shapes by trimming, stemming, and notching, they had been blades corresponding exactly with those produced in a multitude of shops. The shops are, therefore, a necessary complement of the implements of the region, and the implements a necessary complement of the shops. The shops, great and small, are thus definitely connected with the great body of implements of the region, and these implements are directly connected with the dwelling sites of the historic peoples. The practical unity of the stone art of the region is in this way fully established, no type of implement or shaped stone not being fully accounted for by the well established facts and necessary conditions of recent Indian occupancy.

That these demonstrations should be complete and satisfactory, studies were made of quarries of other materials in the neighboring highland where the conditions proved to be the same in every respect. Similar leaf-shaped blades were made and carried out to the surrounding valleys, where they and the implements specialized from them are found closely associated with the more local art products.



SERIES OF FLAKED FORMS ILLUSTRATING PROGRESSIVE STEPS IN THE MANUFACTURE OF PROJECTILE POINTS, ETC., FROM QUARTZITE BOWLDERS.

About one-third actual size. Obtained from shops and villages about Washington City.

It must be regarded as a striking circumstance that a large part of the varied phenomena considered in the monograph are assembled within two or three miles of the capital of the nation, much of it being within the capital city or within the area over which the city streets are now laid out. The greatest aboriginal bowlder quarry known, and the most important implement shops yet observed on the Atlantic slope, are located on Fourteenth Street, two and one-half miles from the Execu-

tive Mansion. Until recently it was hardly suspected that the Potomac-Chesapeake province was so rich in ancient remains. The arts and industries of the historic aborigines were extremely simple, and no striking monument or remains of any kind are found to tell of vanished peoples. Careful exploration has, however, developed evidences of an intelligence and enterprise hardly to be expected of tribes of indolent savages. The use of stone by the prehistoric aborigines was limited to the manufacture of implements and utensils, but their knowledge of the mineral resources of the region was so extensive that no deposit of bowlders, no ledge of flakable stone, no deposit of available stone of any kind, seems to have escaped their attention. Quarrying and manufacture were extensive, and the distribution of the product extended in several cases for a hundred miles or more beyond the source of supply.

The historic tribes of the region are mainly of the Algonquian linguistic stock, the stock of Powhatan and King Philip, and this notable people may be connected by means of the art remains of their numerous village sites with the great body of ancient inhabitants whose domain extended from South Carolina to Nova Scotia. There are some traces of departure from ordinary Algonquian types of art, but these are not decided enough to warrant the assumption that other peoples of independent culture were directly concerned. The culture status indicated by the remains here brought to the attention of students is precisely that of the historic inhabitants encountered by John Smith.

The explorations embodied in this monograph began in 1889 and continued with much interruption until 1894. It is evident from this that the field has been imperfectly covered, for the tide water Chesapeake country comprises upward of 20,000 square miles of territory, nearly every mile of which abounds in important traces of ancient aboriginal occupancy. To visit all and examine all would require a good part of a lifetime. Realizing this, the method was adopted of passing rapidly over the various sections and selecting a few typical examples of each class of sites or groups of phenomena for minute examination. The detailed studies made of these sites serve in a great measure to illustrate the whole subject, and though imperfect in many ways, form nuclei about which additional details can be assembled as they are acquired.

Stone exists in many varieties, forms, and conditions, which differ greatly in the various sections of the country, thus giving much diversity to the manner of its utilization and to the forms employed in art, and many local peculiarities of art phenomena have arisen. Moreover, the tribes of this region were not fully sedentary, and the materials acquired in one section were carried into another, giving rise to much variety in the materials employed by a single people or assembled in a given place. This complexity was also increased to some extent by trade, and no doubt by the undertaking of long journeys for the purpose of securing desired materials. Transportation was confined mainly to the smaller and more laboriously finished articles of use. Unshaped raw materials were not extensively transported, and the large body of the heavier tools and utensils made where material was plentiful were deserted when the locality was abandoned.

The great rivers of Mesozoic and Cenozoic times swept down from the highlands, bearing fragments of all varieties of rocks and depositing them in beds along the margin of the sea. These transported fragments were, when first taken up by the water, sharp and rugged, but by constant rolling they were reduced to rounded forms, and included all sizes from grains of sand and minute pebbles to bowlders and even to great masses. All classes of rocks were thus seized by the floods and carried seaward; but all varieties did not reach the sea, save perhaps as sand or clay. The softer rocks were reduced to powder before the journey was fairly begun; brittle and much flawed varieties, and all friable shales and slates, separated into minute fragments and formed beds of sand and gravel; the tough, hard, homogeneous pieces were rolled and rounded and carried ever onward, refusing to break or to be reduced to dust, and finally rested along the seashore and more especially about the mouths of the great rivers.

The primitive inhabitants of the crystalline highland had to make use of massive forms of rock or of rude angular or slightly waterworn fragments, and the reduction of these to available sizes and forms was a difficult work. But the inhabitants of the lowlands were born to more fortunate conditions. The agents of nature—the floods—had, with more than human intelligence and power, selected the choice bits of rock—the tough quartzite, the flinty quartz, the tough and brittle lavas, the indurated slates, the polished jasper and the beautiful flints—from all the cliffs and gorges of the mountains and had reduced them to convenient sizes and shapes and had laid them down in beds of the shallow estuaries, where, through the subsequent rising of the land and the cutting of the valleys, they were found at the door of the tidewater lodge.

It will be readily seen that these conditions of mineral resources must have had a marked effect on the art of the region and thus on the culture of the natives inhabiting it. One drainage area supplies quartz mainly and the art is quartz art; another supplies quartzite and the art is quartzite art, and so on.

Quarrying begins with the removal of a fragment or mass of material partially buried in the ground. It is but a step further to the uncovering and removal of portions wholly buried, and only another step to quarrying on a large scale. The methods and extent of the quarrying necessarily differed with the peoples and their circumstances, with the nature of the material and with the conditions under which it existed.

Of the details of quarrying operations our knowledge is yet imperfect, though much has been learned in certain directions; and of the tools used in quarrying, aside from those made of stone and left on the sites, no definite information has as yet been obtained. It is quite likely that implements of wood, buckhorn, and bone were used, as in foreign stone age quarries, but traces of these have wholly disappeared from the sites thus far examined. Fire may have been used in some localities as an agent in fracturing masses of stone, but the tidewater region furnished little material, save perhaps quartz, suitable for manipulation by this means. Massive forms of rock are found west of the fall line or western border of the tidewater country. Flint, jasper and rhyolite were quarried far back in the highland, and vein quartz was found, and no doubt to some extent quarried, in a multitude of places over the whole Piedmont region, and down to and even below the margin of the tidewater area. Steatite or soapstone is a tough, massive rock interbedded with gneissic formations, and rarely occurs in detached masses. In the beginning of its use it was secured where exposed on the surface by prying off small masses. The lumps thus secured were ready for the sculptor's chisel. In time quarrying developed and was extensively carried on in many parts of Virginia and Maryland beyond the tidewater border.

The surface or float cobbles were extensively used, but the aborigines came to need more than could thus be obtained, and resorted to digging them from their places in the bluffs. The implement makers seem to have found that the freshly removed stones were more easily worked than surface finds, and quarrying, thus encouraged, was carried, in at least two places, over acres of ground. The bowlders were not always easily loosened and removed, as the rounded stones were held together by a matrix of sand and clay which had assumed the consistency of a sandstone; but the miners did not always penetrate the formation from above or even directly from the face of the outcrop. It happened that in many cases the bowlder beds rested on a surface of disintegrated gneiss exposed in bluff slopes, and by removing the upper surface of this with such pikes as were at hand the bowlders were undermined and easily knocked down. So far as observed, the bowlder deposits containing workable stone in any considerable quantity rest on the gneissic surfaces where they were laid down by the waters of the ancient sea.

Quartz, which was more generally if not more extensively used than any other material, is found in two forms. It occurs in countless veins which penetrate the gneissic rocks over a large district west of the fall line. Being much less destructible than the gneisses, it weathers out in dikelike ridges and breaks up into blocks and angular pieces which spread over the ground in vast numbers. Choice varieties of this vein rock were, without doubt, quarried to some extent, but it was so plentiful on the surface that quarrying was not generally necessary. Carried down by the streams of all periods, it occurs plentifully as pebbles and bowlders in all formations in the watertide region, and was selected or quarried along with the quartzite.

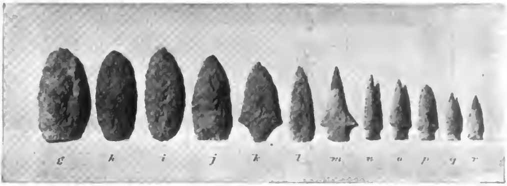
Jasper, flint, rhyolite and other varieties of stone were rather rare within the tidewater districts, occurring sparingly as pebbles, small bowlders and worn fragments in gravel deposits and in the beds of rivers. They were procured, however, by the tidewater tribes from masses in place in the uplands and mountains, the quarries being quite extensive.

Having secured the raw materials from the surface or by quarrying, the next step was either to utilize them unchanged or to shape them for use.

Sharp-edged and pointed stones were used for cutting, digging, etc., and rounded cobbles from the river or from gravel beds were well suited for striking, pounding, grinding, etc. But with these unmodified forms we have little to do, as it is not easy to say that any given specimen was used at all, unless it bears decided marks of use; and decided marks of use may be regarded as giving the object an artificial form, as in the case of the improvised mortars, mullers and hammer stones so common in the Chesapeake-Potomac region.

The shaping processes, by means of which stones were made to assume artificial forms adapted to human needs, are varied and ingenious, and their mastery is of the greatest importance to all primitive peoples. These processes are distinguished by such terms as breaking, flaking, cutting, drilling, scraping, pecking, grinding and polishing. All are purely mechanical; none are chemical, save a possible use of fire to induce changes in the rock in some parts of the quarry work.

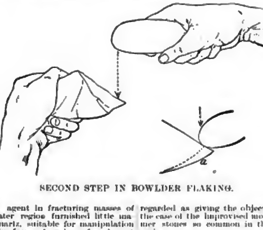
The wide range of manual operations is represented, and these may be conveniently arranged in four



SERIES OF FLAKED FORMS ILLUSTRATING PROGRESSIVE STEPS IN THE MANUFACTURE OF PROJECTILE POINTS, ETC., FROM QUARTZITE BOWLDERS.

About one-third actual size. Obtained from shops and villages about Washington City.

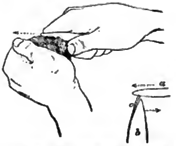
FIRST STEP IN BOWLDER FLAKING.



SECOND STEP IN BOWLDER FLAKING.

groups: 1, fracturing, represented by the terms breaking, flaking, and chipping; 2, incising, including cutting, picking, and scraping; 3, battering, including such acts as bruising, pecking, and hammering; 4, abrading, as in rubbing, drilling, boring, sawing, and polishing. These acts are employed according to the nature of the stone or the results desired; as for example, fracture is employed where the stone to be shaped is brittle, like flint, jasper or quartz; incision is employed where the stone is relatively soft, such as soapstone, serpentine and the like; battering is applied to tough materials, capable of resisting the shocks of percussion, like granite rocks and many of the eruptives. Nearly all varieties are capable of being shaped by grinding and rubbing.

The processes employed in a given piece were determined by the nature of the material, by the intelligence and skill of the workman, by the character of the subject designed, and by a number of minor considerations. Ninety per cent. of the stone implements produced in the tidewater country were shaped by the



FLAKING BY PRESSURE, A BONE IMPLEMENT BEING USED.

a, the bone tool; b, the stone; c, the flake.

fracture process. For convenience of treatment the subject is divided into three sections, which have been noted above. The fourth or abrading process being mainly auxiliary to the others. We will now take up the consideration of fracturing or flaking. The art of flaking stones was extensively practiced in the tidewater region, where ample opportunity is afforded for observing the work in all its stages. The first step in the process, where masses were dealt with, consisted in breaking the material by heavy blows into somewhat approximate shapes and sizes; the second step was roughing out by freehand percussion the blank forms of the various classes of tools desired. The third step was the specialization of forms by direct or indirect percussion or by pressure. It was found convenient and profitable for certain individuals to give exclusive attention to the separate steps—first, quarrying, breaking up the material and selecting pieces in large numbers; second, to roughing out the blank forms and numbers; and third, to the work of trimming, specializing, and finishing. These three well defined steps gave rise to a separate industry, carried on by the same individuals at different times or stages or by distinct groups of experts at convenient times and places. It would seem that the first and second steps, whether performed by one or two groups of workmen, were generally accomplished on the spot yielding the raw material; it would be unprofitable to transport masses of material of which nine-tenths would finally have to be consigned to the refuse heap. The blank forms of the articles to be shaped, worked out so far as thoroughly to test the material and its capacity for specialization, were removed from the source of supply to be finished when convenient or when need demanded.

Where disseminated materials were utilized, and especially in cases of immediate need, all the steps were frequently taken and the perfect implement produced at once; but it is observed that in many cases where the material was sparsely scattered as bowlders or nodules over the face of the country, the work of collection and blocking out was first attended to and the hoards of blanks thus produced were transported and stored, subject to final distribution for specialization or use.

As has been indicated, flaking was employed almost exclusively in the production of projectile points, knives, scrapers, perforators (or drills), hand axes or choppers, notch axes, hoes and picks; it serves to aid in roughing out the forms of various articles finished by pecking and grinding; these are mortars, pestles or mullers, axes, celts, chisels, types, ornaments, and diversional and ceremonial objects.

The flaking tools were probably bowlders selected for the purpose from the multitude of available examples; though few were found that show any considerable evidence of wear, many specimens occur which were more or less battered, apparently by use. With multitudes of natural hammers of choice shape and assorted sizes at hand, it was manifestly useless to shape special tools or to bring in shaped tools from the outside.

The first step after the removal of the bowlders from the bed by the quarryman was to test them for quality of material. As a rule, the removal of a single flake, or at most a very few flakes, enabled the expert workman to determine whether or not the stone was reasonably tractable. The selected material was removed to the shop sites, where the flaker took up the work. The process of flaking appears to have been exclusively fracture by free-hand percussion, the act being a quick, firm stroke, regulated in force by the nature of the resistance to be overcome and by the result observed. The bold but unsymmetric outline of the forms produced and the rather haphazard arrangement of the percussion points preclude the idea that any process capable of accurately adjusting the point of contact between the tool used and the article shaped could have been employed. At best such a method would certainly not be readily applicable to a stone of the refractory nature of quartzite. Though the manner of delivering the strokes seemed sufficiently determined, the precise method of holding the stone shaped is left to conjecture. My own experiments, says Mr. Holmes, have been conducted upon the assumption that it was held in the hand. The account of flaking processes given in the following paragraphs is based on the belief that free-hand percussion with hammers of stone or other hard or heavy material was the exclusive or principal quarry shop process.

The process of manufacture and the steps of development were essentially as follows: Grasping a bowlder in either hand, the first movement was to strike the edge of one against that of the other at the proper angle to detach the flake. The second movement and the third were similar, and so on until the circuit was completed. If no false stroke was made and the stone had the right fractures, these few blows, occupying but as many seconds, gave as a result a typical turtleback—a bowlder with one side faceted by artificial flaking, the other side, save through accident, remaining smooth. If the removal of a single row of flakes were not sufficient, the work was continued until the one side was reduced to a proper degree of convexity, and the availability of the stone for further elaboration was made apparent. If the results thus far reached were satisfactory, the stone was turned in the hand, and by a second series of blows the remaining smooth side was flaked away, when the result was a two faced stone or double turtleback—the incipient blade. With perhaps a few additional strong strokes the rough stone began to assume the appearance of the final form. If at this stage, or if at any preceding stage, the stone developed defects or unmanageable features (such as too great thickness, crookedness, or humps that could not be removed), it was thrown away, and thus became a part of the refuse; and it would appear that all the entire specimens collected, since they were taken by us from the refuse, did develop some of these shortcomings. If, however, the form developed properly, the work was continued into the final stage, which consisted in going over both sides a second and perhaps a third time, securing, by the use of small hammers and by deft and careful blows upon the edges, a thin, symmetric blade.

It is important to observe that when the thin blade was realized, the work of the quarry shop (and the only work of the quarry shop so far as shaping was concerned) was ended. The process and the machinery had accomplished all that was asked of them and all they were capable of accomplishing. The neat, but withal rude, blades, and these only of the shaped products, were carried away. Further work, additional shaping—and such there was in most cases, no doubt—employed other processes and was carried out in other fields. Flakes and fragments suitable for elaboration into implements may have been selected for transportation, but no evidence of this is procurable. The course of procedure just described Mr. Holmes has investigated in the most careful manner, and by experiment has followed every step of the process, and has achieved almost every result. Mr. Holmes found that in reaching one final form many failures were left by the way, and that these failures duplicate, and in proper proportions, all the forms found on the quarry sites. Mr. Holmes was unfortunately prevented from carrying out these experiments as fully as desirable by permanently disabling his left arm in attempting to flake a bowlder of very large size.

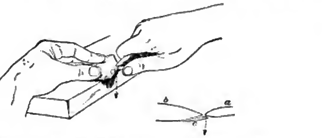
Mr. Holmes further found by these experiments—and the conclusion is a most important one—that every implement resembling the final form here described, and every blade-shaped projectile point made from a bowlder or similar bit of rock not already approximate in shape, must pass through the same or nearly the same stages of development, leaving the same wasters, whether shaped to-day, yesterday, or a million years ago; whether in the hands of the civilized, the barbarous or the savage man.

We are not prepared to say at just what point in the shaping of the blade or implement from quartzite and each of the other stones the percussion ceases and the pressure processes take up the work. It is certainly later in the quartzite than in any of the others because of its coarse grain and exceeding toughness and the consequent lack of thin and sharp edges on which the pressure tool must take hold.

In the method most readily available for the final steps a blank form or a flake having the approximate shape was held firmly between the fingers and thumb of the left hand. A firm piece of bone having a rather thin edge or angle like that of a three-cornered file was taken in the right hand and set upon the sharp edge of the stone and at right angles to it so firmly that a slight cut or notch was made in the bone; then, with a quick, firm movement of the right hand, met by a similar movement of the left, the bone was made to move across the edge of the stone, in doing which it took with it a flake, varying in length, width and depth with the skill and power of the workman, the nature of the stone, etc. A rapid repetition of this operation, accompanied by a proper resetting of the tool, quickly reduced the piece if it worked readily to almost any desired outline. The same result was obtained in various other ways, but always by means of suddenly applied or spasmodic pressure. The blank form may have been held down by the fingers on the edge of the stone, as shown in our engraving, and the point of the bone held in the other set so as to catch the edge of the stone to a width corresponding to that caught by the notched bone in the other position, when a quick downward pressure upon the flaking tool would remove the flake. Again, in larger work, where greater force was required to remove the flakes, a tool large enough to place against the arm or chest of the operator may have been used. In this way much additional force could be thrown into the spasmodic movement. Another device, practiced by some tribes, consisted of a notched or forked bone or pincers, which was set upon the sharp edge of the blank and given a sudden twist, thus removing the flake. These operations apply exclusively to implements of leaf blade type and to minute forms of other origin; the various ruder and heavier variety of tools were shaped by percussion exclusively.

The subjects of battered and abraded stone implements and incised or cut stone utensils are also treated in Mr. Holmes' interesting monograph.

Our engravings show the various steps in bowlder flaking and a series of flake forms showing progressive steps in the manufacture of projectile points from quartzite bowlders, and also a group in plaster, illustrating the work carried on in an aboriginal quarry workshop. This quarry group was prepared by Mr. Holmes as an exposition exhibit for the Columbian Exposition in Chicago, 1893. It is intended to exemplify a great art of the race—the shaping of stone by flaking processes. After the return of the group from the Exposition, Mr. Holmes conceived the notion that the figures could be taken to Piney Branch and placed in an actual quarry, thus more graphically portraying the ancient operations. A site was selected for the purpose on the margin of the gulch near Fourteenth Street, Washington, where some great oaks grow on the beds of ancient refuse. But before the project could be carried out, Mr. Holmes was called away from the work permanently. Messrs. Cushing and Dinwiddie, of the Bureau of Ethnology, generously took up the work, and the result is indicated in an interesting review which accompanies this monograph.



FLAKING BY PRESSURE, A BONE POINT BEING USED, THE IMPLEMENT TO BE SHAPED RESTING ON A SUPPORT.

ROMAN MEDICINE STAMPS

IT is somewhat curious that medical specialism and proprietary medicines appear to have had their advent about the same period. That the latter owe their origin to the Roman specialists we have ample proof from the medicine stamps or stones which have been discovered from time to time on the sites of old Roman cities in France, Germany, etc., all of which agree in their general characters. These stones generally con-

IMPRESSION FROM A CIRCULAR ROMAN MEDICINE STAMP.

sist of small quadrilateral or oblong pieces of a greenish schist or steatite, engraved on one or more of their sides. The inscriptions are in small Roman capitals cut intagliate, and consequently reading on the stone itself from right to left, but making an opposite impression when stamped on any plastic material. The stamps are usually engraved with the names of the medical practitioners to whom they pertained, also the names of some special medicine or medical formula, and the disease for which the medicine is prescribed or recommended, and there can be no doubt that they were employed by the Roman doctors for marking their drugs, a practice apparently carried on at the various stations throughout Europe.

Most of the stamps discovered are inscribed with the

A PERFECT ROMAN MEDICINE STAMP.

names of medicines or preparations applicable for affections of the eye, and the diseases, when specified, are invariably of an ophthalmic nature. It is therefore probable that these stamps were used by oculists alone. The Romans employed the term collyria to both solid and liquid applications for the eye. The solid collyria were composed of various ingredients with a base of gum and starch, and wrought to a pasty consistence. They were used in almost every stage of disease of the eye. Some were known by the names of the oculists who invented them, others from their color, or from the

name of some great personage whom it may have cured. The stamps were employed to impress the soft substance with the required inscription, and also to stamp the labels (pittaria) attached to the vessels of the liquid collyria. Marcellus, in his work "De Medicamentis," specially praises the collyrium known under the name of "Evodes." He directs it to be dissolved and diluted in water, and introduced into the eyes with a probe.

The stamp of this collyrium has been discovered, and bears the following inscriptions: On one side, "The Evodes of Lucius Vallatinus for Cicatrices and Granulations;" on the other, "The Mild Crocodes of L. Vallatinus for Affections" (of the eyes).

From this it is evident that Vallatinus prepared more than one special application for the eyes.

A stamp found at Bath in 1731 bears the following interesting inscription:

"The Lenden Mellinum (or Golden Yellow Collyrium) of T. Junianus for clearness of vision," from which we may infer Junianus sold his "Golden Yellow Collyrium" to the colonists and natives of Bath some 1700 years ago. The popular name "Golden Ointment," given to an application for the eyes, is therefore of greater antiquity than is generally supposed, and it may interest pharmacists to know that it was originated by a Roman oculist.

Two other stamps discovered bear the following inscriptions:

"The Dialepidos or Copper Collyrium of Marcus Julius Satyrus for granulation of the eyelids."

"The Myrrh Collyrium of L. J. Ireuis to be used twice a day mixed with an egg at the commencement of ophthalmy."

Another stamp found at Kinchester in Herefordshire bears the following inscriptions on its sides:

1. "The Anicetum or Infallible Collyrium of F. Vindacius Ariovistus."

2. "The Nardinum of Spikenard Collyrium of F. Vindacius Ariovistus."

3. "The Chloron or Green Collyrium of T. F. Vindax Ariovistus."

These are described by Dr. Simpson in the Monthly Medical Journal for 1851. A stamp discovered at Wroxeter in 1808 is inscribed as follows: "The Dialebanum of Tiberius Claudius, the physician, for all complaints of the eyes, to be used with egg." This stamp is now in the Shrewsbury Museum.

The most perfect stamp yet discovered (of which we give an illustration) was found at Tranent, near Edinburgh, and is now in the museum of the Society of Antiquaries of Scotland.

ROMAN OCULIST'S STAMP FOUND AT TRANENT, E. LOTHIAN, N. B.

The Roman practitioners seem to have pursued in regard to old cicatrices of the eye a treatment which is not followed by their successors in modern times, as they used various collyria for the purpose of dyeing or changing the color of these white cicatrices, and thus imparting to them some kind of tint that rendered the appearance of the eye, and the distinction between the transparent cornea and its cicatrices, less marked and striking. For this purpose galls appear to have been largely used.

It is worthy of note that Stolus, the first British medical practitioner mentioned in the pages of medical history, and whom Galen describes as celebris some 1700 years ago, originated the "Cinnabar Collyrium."

Altogether over sixty Roman oculist stamps have been discovered in different parts of Western Europe at various periods, which proves that medical specialism must have flourished in those early times.—Pharmaceutical Journal.

THE FINDING OF THE REMAINS OF THE FOSSIL SLOTH AT BIG BONE CAVE, TENNESSEE, IN 1896.*

The fossil sloth bones found in Big Bone Cave, Tennessee, illustrate an investigation at one of the points of contact between paleontology and archæology. They explain an effort made during the last several years by the Department of Archæology and Paleontology of the University of Pennsylvania to settle the question of man's antiquity in North America through a study of the association of human with animal remains in caves. Turning away, for a time, from mounds, village sites and buried cities, we have sought the help of the naturalist in a systematic attempt to penetrate the crust of recent earth under foot, to trace man through a mixture of the familiar vestiges of such animals as the deer, the bison, the bear, the beaver, the muskrat and the wolf, still existing in the American forest, and to follow him down into that older world layer next below called the Pleistocene. There we have endeavored to find, if possible, his bones still associated with the remains of the extinct mastodon, the mammoth, the tapir, the giant beaver and the fossil sloth.

Much remains to be done over a wide territory, before the evidence of American caves, for or against man's geological antiquity, can be adequately collected or reasonably summed up. But already, in the territory examined in the eastern United States and Central America, some landmarks seem to have been established in the pre-Columbian darkness.

Here, then, to return to the particular specimens presented by me, are bones which, from the point of view of anthropology, might be presumed to be very ancient, older than the pyramids of Egypt or the oldest inscribed brick yet found in Babylonia, but which, it must be confessed, appear quite modern. I removed them with my own hands out of the floor earth of Big Bone Cave, Van Buren County, Tenn., in last May (1896), while conducting thither an expedition for the Department of American and Prehistoric Archæology of the University of Pennsylvania.† Strange to say, many have articular cartilage clinging to them. Most have been gnawed by small rodents while still retaining their juices, and for these reasons and because, as we shall see later, they form part of a set of bones, doubtless of one and the same animal, obtained from Big Bone Cave first in 1885, next in 1884, and now last by me in 1896, they may be classed as pertaining to the most modern looking if not the most interesting series of remains of the extinct animal ever found in the United States. In this case, since the position and the association of the other specimens alluded to of 1885 and 1884, previously found in the same cave by farmers, were not observed, the bones here shown constitute the only remains of this Big Bone Cave animal, whose relation to surrounding facts bearing upon their age has been studied so as to furnish some reasonable conclusion as to how and when the creature got into the cave, and whether or not it was a contemporary of the Indian in the Southern mountains.

Fig. 1.—BIG BONE CAVE

In the first place, it should be said that the bones did not come from a human culture layer nor from a den of large carnivora. Neither were they found at a site where the cave explorer would have chosen to dig, but rather at a spot where all the conditions of exploration seemed unfavorable. They were rescued from one of the subterranean galleries at the last moment, after the whole cave had been rifled for saltpeter.

About one mile from the left bank of Caney Fork River, and one mile above the mouth of a confluent called Dry Branch, in Van Buren County, Tenn., probably 1,000 feet above the sea, Big Bone Cave opens from the carboniferous limestone upon the head of the "Beech Cove," one of the secluded ravines called "coves" that furrow the western slope of the Cumberland table land.

To our surprise, the point of interest in Big Bone Cave lay far beyond the reach of daylight. It was only found after turning to the right from the main tunnel and following a small bifurcating passage for 900 feet.

Laden with pickax and shovels, baskets, instruments, candles and provisions, now crouching where the roof lowered, now clambering upon a log across an intersecting crevice, eight or nine feet deep, we followed the lead of Priest, until directly on the footway a spot was reached where, in the utter darkness, beyond the range of the continued haltings of men, and probably of large animals, at a point where no human culture layer, under ordinary circumstances, could have been formed, these remarkable bones of the sloth and all other sloth bones, known to have been previously removed from the cave, were found. Elsewhere the evidence of the relation of animals and men to the cavern, whatever its character, had been destroyed.

Fig. 2.—CLAW WITH CARTILAGE AND HORNY SHEATH OF THE SLOTH MEGALONYX.

From the J. P. Wetherill collection at the Academy of Natural Sciences of Philadelphia. One of the bones found in Big Bone Cave before 1896, and unquestionably a part of the same young animal represented by the other illustrations. Actual size.

The record of these bones is, therefore, very different from that of animal remains dug out of the rock shelters of Europe, or from that of specimens derived from any layer of caked human rubbish where savages have been wont to take subterranean refuge. Men certainly did not bring them into the cave. Frost had never reached them. Neither would change of temperature have affected them where they appeared to have rested in the dry earth in an unchangeably cool air since the time of their deposition.

Let us describe this place. The roof has expanded over several branching alcoves, partitioned head high by screens of eroded rock. Mysterious crevices in the ceiling rise above us beyond the reach of candle light. There are no stalactites and we feel no trace of dampness. The severe outside heat of the Southern spring has been reduced to a dry and cool subterranean temperature of 55° F. Where a flanking screen narrows the gallery to a width of three and four feet, the earth is soft and mealy under foot and covers the whole floor, rising in a cloud of dust when disturbed by a kick. This floor deposit proves on examination to consist of a noxious and volatile mantle of dry, loose excrements, mixed with vegetable remains, covering up and spoiling by its intermixture the nitrous earth resting in lumps beneath it, and thus sufficiently explaining why, as far as saltpeter digging was concerned, that part of the cave had never been disturbed.

We were directly upon the cave path, where back and forth over the dusty manure all footsteps of all saltpeter hunters, all white men, all Indians, choosing to penetrate deeper into the cave, must needs have passed. Their trampling had draggled the surface, kicking earth into it from other areas, or dropping "peter dirt" upon it from bags. Moreover, charred pieces of resinous pine, Pinus mitis, twigs of hazel, Corylus americana, and fragments of burnt cane, Arundinaria tecta, strewed the surface, representing doubtless the remains of the torches of such white niter hunters as had not had lamps or candles, and, we may reasonably suppose, of the Indians who had preceded them. The appearance of this surface film, then, which I have called

LAYER 1

(Two to three inches thick),

thus disturbed for two or three inches, and scattered with lumps of nitrous earth and with these burnt sticks, was sufficient to demonstrate that human beings had visited the cave, if no further proof of the fact had existed. Over and above the certainty that white men had long passed and repassed the spot, and that many of the torch ends, and particularly the pieces of pitch pine which suggested the splitting agency of iron tools, might be referred to them, it seemed reasonable to suppose that some at least of the pieces of charred cane resembling fragments of Arundinaria found by us mingled with aboriginal bones in the sepulchral chasm

* Abstract of paper by Henry C. Mercer, curator of the Museum of American and Prehistoric Archæology at the University of Pennsylvania, read before the American Philosophical Society.

† I take pleasure in returning the thanks of the department and of myself to our vice president, Dr. William Pepper, who alone defrayed the expenses of this expedition.

at Lookout Cave) had been cast away at the spot by Indians.

Our party of four, Mr. G. B. Johnson, James Priest, my assistant, Joseph Musselman, and myself, had stopped, and Priest, our guide, holding down his candle, pointed to a hollow caused by digging in the mass of dry manure, where he, about 1884, while filling several bags full of the "fertilizer," as he called it, for his garden, and later Mr. Johnson himself, on a similar errand, had found several vertebræ, ribs, the pelvis and the skull with teeth of a large animal (the extinct sloth), which, after remaining for some time at the house of Mr. Johnson, had been sent to Nashville and sold. For this reason, and as well testified by the letters to me of Prof. J. M. Safford, State geologist of Tennessee, who first advised my exploring the cave, let it be said in parenthesis that without doubt the sloth skull now in the possession of Prof. Safford, at Nashville, and which I have been unfortunately unable to obtain from him for comparative study, is the skull thus found by Priest, and because this skull and the other bones belonging to Prof. Safford, corresponding to those described as found by Priest and Johnson at this place, also show cartilage, and further because the evidence indicates that there was only one sloth at this point, with no reason shown why there should have been more than one, and because it appeared that no other spot adapted for the discovery of fossil bones had existed at the entrance of the cave, for these reasons, I believe that the Nashville bones and my set go together as parts of one animal; and further, as first suggested by Prof. Safford and now shown by my examination, let me add that still another and a third set of sloth bones, belonging to the Academy of Natural Sciences, of Philadelphia, herewith shown (see Fig. 2 for one of them), found by a farmer in the cave and described by Dr. Harlan in 1835, also showing cartilage equally fresh in appearance and referable to a young animal (because of the loose epiphyses) may well be believed to constitute skeletal portions of the same individual.

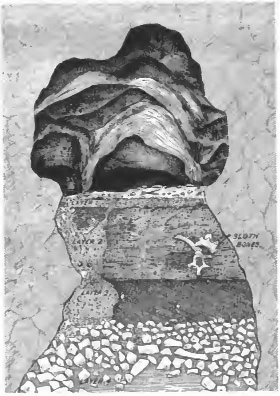


FIG. 3.

Diagram showing a vertical section of the gallery in Big Bone Cave where the sloth bones were found. Layer 1 (2½ inches), disturbed surface rubbish with charcoal torch ends. Layer 2 (2 to 2½ feet), dry loose rat excrement, animal and vegetable remains, etc., with sloth bones. Layer 3 (1 foot), crusted lower portion of rat excrement and vegetable remains formed before the advent of the sloth bones. Layer 4 (of undetermined depth), loose pieces of nitrous clay, dry and hard, mixed with manure. The disturbance resulting in the intrusion of torch ends and other objects into the deposit as far as Layer 4, caused by burrowing rats, is seen against the left cave wall.

These subsequently arrived at conclusions, however, did not concern us when, first pausing in the candle light, we placed our tools and baskets upon the ground to listen to the account of Priest. Our hope of finding more bones depended upon the chance that he had not dug up the whole floor and that other remains, resting beyond the limit of his digging, had escaped him and remained to reward our search.

Down through the manure and nitrous earth resting beneath it, from nine in the morning till five in the afternoon, beginning where the consistency of the deposit showed that Priest and other diggers had left off, we worked in the dim candle light, until our hunting had accomplished its object, and until the walls of our trench revealed the facts herewith described, and first that of a sequence in time marked by the layers that had accumulated upon the foothold, and of which two epoch-denoting divisions confronted us. They consisted of (below and older) a water-deposited nitrous clay, resting upon the bottom rock, standing for a time when the cave was wet, and (above and later) the manure previously referred to, testifying to an epoch when the cave was dry, and to the latter division with its subdivisions described as Layers 1, 2 and 3, and hence to the later time belong the sloth bones here shown. One after another they were found in the dry manure, which, lying invariably under Layer 1 above described, I have called

LAYER 2

(Two to two and a half feet thick. See Fig. 3.)

As we worked forward through this layer with shovel, hands and trowel to where it thinned out and the saltpeter earth now removed had formed the foothold beyond it, we found it to consist almost entirely of well preserved, dry excrements of the cave rat, Neotoma magister, which intermixed in lesser quantity with coprolites of porcupines, Erethizon dorsatus, formed the conspicuous ingredients of the mass. In consistency like a bin of oats, the deposit answered every disturbance with a cloud of pungent dust. Nuts, sticks, fur and moss were easily seen in it by candle light, but more minute search in the cave and a subsequent study of the specimens preserved revealed at various points the seeds, grass, bark, leaves, hair and small botanical fragments described later. In the midst of this interesting rubbish, often in contact with seeds, nuts and hair, appeared the twelve sloth bones found, protruding from the vertical side of the trench at depths of from eight to fourteen inches.

The first bone found (see Fig. 4) was an epiphysis of a humerus. Then came a well preserved vertebra No. 2 (see Fig. 5), found at a depth of one foot eight inches below the surface and one foot from the right wall of the cave. The small coprolites touched it on all sides. Just above it lay a small twig of wood, and close to it several bones of bats, described later, while both above and below it we noticed wads of fine hair. The deposit was exceedingly dry, and its removal filled the cave with suffocating dust clouds. Immediately in contact with bone No. 2, as we worked horizontally into the bank, lay bones Nos. 3, 3½ and 4, two unseparated vertebræ with a loose epiphysis resting between them, directly under which we found two gnawed hickory nuts and an acorn.

FIG. 4.

First bone found (in Layer 2, depth about 10 inches), epiphysis or unknitted end of the humerus of a young sloth, Megalonyx. Photographed, resting upon the characteristic rubbish of Layer 2 found around it. 1. Bat's jaw, Adelonycteris fusca. 2. Hickory nut and fragment gnawed by rodent, Hicoria glabra. 3. Excrement of large mammal, possibly sloth. 4. Felted hair of bats, rats, and porcupines mixed with a woolly fur, possibly belonging to the sloth itself. 5. Bones of the bat, Adelonycteris fusca. The background is composed of a mass of dry coprolites of cave rats, brown dusty earth, and fragments of hard cave clay, "petet dirt."

FIG. 5.

The second bone found (in Layer 2, depth 1 foot 8 inches). Dorsal vertebra.

As we advanced vertically into the manure, another vertebra, the fifth bone found, bone No. 6, the heel bone (calcaneum), and bone No. 7 (the astragalus), were revealed lying but a few inches apart. With deep interest I removed them. Just below the fifth bone, at which point the deposit had hardened considerably (Layer 3) and was mixed with fine pieces of saltpeter earth, another acorn was found, and still another under the astragalus.

On that day, May 6, 1896, at 3:15 in the afternoon, with the wind blowing from the north, a slight draught of air wafted the currents of dust inward as we worked, while, to testify to the open communication of that part of the gallery and the outer world by means of the roof holes, a small cricket appeared, crawling upon the disturbed earth as we worked at the third bone.

A considerably gnawed rib fragment (see Fig. 7) was followed by a loose epiphysis, and a final vertebra, the tenth bone found, lay against the rock wall on the right, not much more than eight inches below the surface, where, close to the top of the deposit and still against the wall, the wads of hair were best preserved. Here also were found a gnawed butternut, several pieces of grass, several small bat bones and dung as usual. The position of these latter objects close to the wall caused us to suspect that they had slid down from the surface, just as close to the left side twigs of leaves had probably been intruded in the rat holes. But the objects found at or below the position of the other bones we regarded as of equal age with them, and as truly indicative of the nature of the layer.

Our observation of the position of all the bones showed that they were not (with the exception of the two vertebræ and epiphyses) to skeletal order; several epiphyses were loose; the calcaneum (heel bone) lay close to the vertebræ; the single rib found was broken and turned. Unquestionably the bones had been

drugged and twisted out of place (inferentially by the gnawing rats or the porcupines) since their deposition. Some may have been carried away to hidden crannies through burrows noted later communicating with the rubbish.

(To be continued.)

THE FORESTS OF ALASKA.

THE great maritime forest of northwestern North America, which at the south embraces the redwoods of California and spreads over western Oregon and Washington, terminates on the Alaskan coast on the eastern shores of Kadiak Island, just below the fifty-eighth degree of north latitude. Taken as a whole, this coniferous forest is unequaled in productiveness and in the size, beauty and value of its trees. Not only is the redwood the largest of all conifers, with the single exception of its relative of the Sierras, which excels it in bulk of stem and branches, but not in height, but in this maritime forest are found the largest spruce tree and the largest hemlock in the whole world. Of the arbor-vitaes here grows the giant of its race; and of all the cypress tribe none can equal Lawson's cypress in majesty of port. Here, too, the alder becomes a great tree, and firs assume their noblest proportions.

To-day, however, we would speak more particularly of that part of this forest covering the coast mountains of southeastern Alaska, and which in many of its general features resembles the forests of Puget Sound and of western British Columbia, although the Douglas spruce, the most abundant tree on the shores of Puget Sound and Vancouver Island, where it surpasses all its associates in height and in size of stem, does not reach Alaska. The white fir (Abies grandis), which is so conspicuous with its tall pyramids of lustrous dark green foliage on the shores of the Gulf of Georgia, is absent, too, from the Alaska forest, as is the great-leaved maple (Acer macrophyllum), abundant in all the coast region further south. The arbor-vitæ (Thuya gigantea), which is common and of fine size on Prince of Wales Island and on the southern part of the Cleveland Peninsula, is rare, if it exists at all, north of latitude fifty-six; and the coast forest of southeastern Alaska is composed almost entirely of two trees, the Sitka spruce (Picea Sitchensis) and Merten's hemlock (Tsuga Mertensiana). From the edge of tidewater these two trees grow up to the timber line, which varies in elevation from 2,500 to 4,000 feet, everywhere in dense, serried masses, like the blades of grass in a meadow, covering all islands and the seaward slopes of the mainland mountains, which shut off the moisture from the dry interior. Sometimes the spruces predominate, especially toward the north; sometimes the hemlocks are more abundant, and often the two are mixed in nearly equal numbers. Through this forest the Sitka cypress (Cupressus Nootkatensis) is scattered, usually at elevations of about 1,000 feet above the sea level, although it often descends to the water's edge. It grows, not in large bodies, but often in numbers sufficient to enliven the somber spruces and hemlocks with the cheerful yellow tints of the graceful frond-like branchlets which descend from the wide-spreading branches of this splendid tree, unrivaled by any other American conifer in the beauty and value of its wood. On the margins of the little flats and beaches which occur only at the mouths of streams—for on the Alaska coast the mountains usually rise abruptly from the sea—alders of two kinds and the lovely Sitka willow light the borders of the forest; and alders sometimes extend up the banks of streams or hang over rocky sea cliffs. On sloping seashore bogs, rich in mosses and studded with many charming herbs and dwarf shrubs, Pinus contorta, the only Alaskan pine, occurs rather sparingly; and on Baranof Island, near the town of Sitka, Patton's spruce (Tsuga Pattoni), which is probably widely distributed over the coast mountains at high altitudes, descends with a few small individuals nearly to the sea level. These, with the addition of the balsam poplar, which is only seen near streams, and the little Rocky Mountain maple (Acer glabrum) are the only trees of the coast forest of southeastern Alaska, which is remarkable in its poverty of species, in its richness in individuals and in the size these attain in the thin soil, a few inches deep at best, and often on the nearly perpendicular slopes of these glacier-swept hills. They are wonderful, too, in the deep mosses of the forest floor, and in their impenetrable undergrowth of blue berries of many varieties, salmon berries, menziesias, and the terrible devil's club (Panax horrida), which so cover the ground with their entangled stems that travel through the woods is practically impossible.

As compared with trees in forests further south, those of Alaska are not large, although spruces and hemlocks a hundred and fifty feet high, with trunks three or four feet in diameter, are not rare at the sea level as far north as Baranof Island; ascending from the shore, however, the trees rapidly decrease in size and near the timber line become small and stunted, as they often do at the sea level at the heads of the numerous estuaries and fiords cut deeply into the mainland coast range.

The deepest and most interesting of these fiords, the Lynn Canal, a narrow continuation of Chatham Strait, extends a hundred miles northward from the coast nearly to the sixtieth degree, and at its head is fed by the waters of the Chilkat, the Chilkoot and the Skagway rivers, swift mountain streams, which afford difficult passage across low passes into the interior to the headwaters of the great western tributary of the Yukon. The forests at the head of the Lynn Canal differ somewhat from those in the region nearer the coast. The narrow bottom lands are covered with masses of balsam poplar or with the so-called green alder, which here becomes a tree fifty feet high. The spruce is still abundant at the river level and on the lower slopes, but it is everywhere small and stunted. The hemlock also occurs here, but only sparingly, and not of large size. The pine is seen on the flats and at considerable elevation on the hillsides, but here its leaves are broader than those of the coast trees, and it is passing into the variety Murrayana of the interior plateau, the Lodge pole pine of our northern Rocky Mountains. A white birch is very common at low elevations, and is more like the birches of Siberia and northern Japan than any described American species, and growing with it is Acer glabrum, which is certainly the most widely distributed of all the North American maples, and probably the most boreal member of the genus, and Patton's spruce is at the timber line.

When these passes from the humid coast region to the dry interior are crossed, an entirely different forest is encountered. The hemlock and the Sitka spruce have disappeared, and the largest tree in the open scattered groves near the shores of Lake Bennett and Lake Linderman is a fir (Abies lasiocarpa). With it grow stunted white spruces (Picea alba), which in greater or lesser abundance and mingled with balsam poplars, birches and alders are scattered over the basins of the Yukon and its tributaries for hundreds of miles, and finally reach the Pacific coast on Kotzebue Sound within the Arctic Circle, and nearly five degrees north of Kadiak Island, where the forests of southeastern Alaska give way to a growth of grasses and low alders and willows.

Trees cannot be cut lawfully in Alaska for timber or fuel, for there is no law which permits the sales of stumpage or timber lands, and no law relating in any way to the forest but the one which forbids all shipment of wood from the Territory. There are a few sawmills in Alaska, however, and the number will soon be increased, and a large quantity of fire wood is consumed at the salmon canneries and quartz mines, but the government gets nothing for it, and is powerless to prevent damage to the public domain. Fortunately, the climate of southeastern Alaska is so humid that forest fires are rare, and never very destructive, and reproduction is sure and rapid. These forests, therefore, even with American methods, will not soon or easily be destroyed; and here and to the southward along the coast ranges and islands of British Columbia through nine degrees of latitude from Cross Sound, at the north of Chicagof Island, to the Straits of Fuca, is now the greatest continuous body of coniferous timber in the world, almost unmarked as yet by the ax, safe from fire and of easy access, from which the world will be able to draw great stores of material when the redwoods and Douglas spruces of the South have fallen, and our south Atlantic and Gulf shore pineries are only dim memories.—Garden and Forest.

THE MINISTRY OF LEAVES.

IN the body of an animal there is always going on a process of slow combustion; oxygen taken in by the lungs enters into union with carbon derived from the food, carbonic acid is formed, and heat evolved. Every atom of carbon disengaged from oxygen by the plant represents an expenditure of heat upon the leaves equal to that developed during its combination with oxygen in the animal system. In the leaves this heat disappears; it becomes latent, and is stored up as potential energy. When we burn a piece of wood, not only is the carbon which the tree originally extracted from the air restored to the atmosphere in the form of carbonic acid, but the heat given out by the burning wood corresponds exactly to the amount by which the sunbeams were chilled through the activity of the leaves while the wood was growing. Robbing the sunshine of its heat in this way, leaves must act as refrigerators. Leaves exert a further cooling influence on account of the watery vapor they are constantly giving off, for whenever water evaporates, much heat is rendered latent and ceases to be discerned by the senses. A man is said to exhale about one hundred gallons of carbonic acid in a day. Boussingault estimated that a square yard of leaf surface, reckoning both the upper and lower sides of the leaves, can, under favorable circumstances, decompose rather more than a gallon of carbonic acid in a day. At this rate, one hundred square yards of leaf surface should keep a man going with oxygen. A single tree would suffice for quite a number of people, for, according to the late Prof. Asa Gray's computation, even a moderately sized elm possesses five acres of leaf surface.

Widely as they differ in appearance, a lung and a leaf are constructed on very similar principles. In the lungs the air tubes are subdivided into an infinite number of small ramifications, around which the blood vessels are distributed in an extremely fine network. By this arrangement an immense surface is exposed to the air, with comparatively small expenditure of space. Through the delicate membranous walls of these fine tubes the air penetrates into the blood vessels beneath, and from the blood carbonic acid diffuses into the air tubes, and is exhaled. The typical leaf, again, is a thin expanded plate, offering a large surface to the air relatively to its mass; its lower stratum is honeycombed with innumerable air spaces and intercellular passages, which communicate with the external air through thousands of pores or stomata. Oxygen and carbonic acid are exchanged through the walls of the leaf cells very much as in the lungs, but in the reverse order. The flattened form of the leaf secures illumination and promotes evaporation; lungs, having no need of light, are shaped to suit the space available. The resemblance between the submerged leaves of aquatic plants, such as the water buttercup, and the external gills or branchiæ of the young tadpole and other amphibians, is particularly striking. Both organs are cut up into fine, threadlike segments, giving them a fringed or featherlike appearance. The large absorbing area thus presented to the water facilitates the absorption of the dissolved gases. Leaves are, however, organs of nutrition. This resemblance to respiratory organs arises entirely from the fact that by far the largest proportion of a plant's food is absorbed in the gaseous condition. Referring to this adaptation of the leaf, Johnstone, in his "Agricultural Chemistry," says: "How beautiful is the contrivance of the expanded leaf! The air contains one gallon of carbonic acid in two thousand five hundred, and this proportion has been adjusted to the health and comfort of animals, to whom this gas is hurtful. But to catch this minute quantity, the tree hangs out thousands of square feet of leaf in perpetual motion, through an ever-moving air; and thus by the conjoined labors of millions of pores, the substance of whole forests of solid wood is slowly extracted from the fleeting winds."

Chlorophyl itself owes its formation to light; but to conceive how the ethereal undulations, acting on the living substance of a leaf cell, can elaborate a structure so complex, baffles imagination. How marvelous are the properties of light and how manifold its adjustments to differently constituted materials! Light is at once the most useful of natural agencies and the most beautiful of physical phenomena. And yet it must be tempered to our vision. Painful and blinding the glare from rock or desert, but what more grateful than the sight of fresh green meadows! In contact with the grass light is purified from rays which fatigue and injure our eyes. This tempering of the sunshine is another of the many benefactions we owe to the ministry of leaves.—Alex. S. Wilson, in Knowledge.

HOT SODA WATER DRINKS.

HOT soda is served by drawing 1 or 1½ ounces of the flavoring preparation, sirup, extract, juice, etc., into the mug, adding cream and sugar, if these be required, filling the cup with hot water, and serving with a spoon. The amount of flavoring stated is intended for an 8 ounce mug. Sometimes the beverage is topped off with whipped cream or with a spice. Here are some formulas:

Chocolate.

Baker's fountain chocolate ......1 pound.
Sirup .... 1 gallon.
Extract vanilla, enough.

Shave the chocolate into a gallon porcelained evaporating dish and melt with a gentle heat, stirring with a thin bladed spatula. When melted remove from the fire and add one ounce of cold water, mixing well. Add gradually one gallon of hot sirup and strain; flavor to suit. Use one ounce to a mug.

Hot Egg Chocolate.

Break a fresh egg into a soda tumbler; add 1½ ounces chocolate sirup and 1 ounce cream; shake thoroughly, add hot soda slowly into the shaker, stirring meanwhile; strain carefully into mug, top off with whipped cream and serve.

Hot Chocolate and Milk.

Chocolate sirup ....1 ounce.
Hot milk.............................4 "

Stir well, fill mug with hot soda and serve.

Coffee.

(1) Coffee sirup may be made by adding boiling water from the apparatus to 1 pound of coffee, placed in a suitable filter or coffee pot, until 2 quarts of the infusion are obtained. Add to this 3 pounds of sugar. In dispensing, first put sufficient cream in the cup, add the coffee, then sweeten, if necessary, and mix with the stream from the draught tube.

(2) Mocha coffee (ground fine) ...... 4 ounces.
Java coffee (ground fine) ...... 4 "
Granulated sugar.............. 6 pounds.
Hot water .... q. s.

Percolate the coffee with hot water until the percolate measures 72 ounces. Dissolve the sugar in the percolate by agitation without heat and strain.

Lemon.

Lemon sirup is, of course, best prepared when the juice of the fruit is squeezed into the glass, powdered sugar and hot water added, and the whole shaken well in a shaker. When this is not possible, lemon juice previously prepared is the best substitute. Try the following formula:

Lemon juice ....1 ounce.
Hot soda sirup .... 4 "

Mix with stream from draught tube.

Ginger.

Fluid extract of ginger.......... 2½ ounces.
Sugar.................................40 "
Water, to .... 2¼ pints.

Take 10 ounces of the sugar and mix with the fluid extract of ginger; heat on the water bath until the alcohol is evaporated. Then mix with 20 ounces of water and shake till dissolved. Filter and add the balance of the water and the sugar. Dissolve by agitation.

Hot Egg Coffee.

Break a fresh egg into a soda tumbler; add 1 ounce coffee sirup; shake thoroughly, add hot milk slowly into the shaker, strain carefully into mug, top off with whipped cream and serve.

Cocoa Sirup.

Cocoa, light, soluble. .... 4 ounces.
Granulated sugar....................2 pounds.
Boiling hot water ....1 quart.
Extract vanilla.........................1 ounce.

Dissolve the cocoa in the hot water, by stirring, then add the sugar and dissolve. Strain, and when cold add the vanilla extract. To dispense,

Cocoa.

Cocoa sirup........................... 2 ounces.
Cream.................................. 1 "

Turn on the hot water stream and stir while filling. Top off with whipped cream.

Hot Soda Toddy.

Lemon juice ....2 fl. drachms.
Lemon sirup................................1 fl. ounce.
Aromatic bitters...........................1 fl. drachm.
Hot water, enough to fill an 8 ounce mug.

Sprinkle with nutmeg or cinnamon.

Hot Orange Phosphate.

Orange sirup .... 1 fl. ounce.
Solution of acid phosphate ...... 1 fl. drachm.
Hot water, enough to fill an 8 ounce mug.

It is prepared more acceptably by mixing the juice of half an orange with acid phosphate, sugar and hot water.—Pharmaceutical Era.

A French inventor has made use of a rubber tube as a core on which to mould pipes of cement and sand. To make a continuous conduit in the ground, a trench is dug, and at the bottom of this is placed a layer of cement mortar. On this rests the rubber tube, which is surrounded by canvas, and inflated. The remainder of the trench is then filled with cement mortar, and as soon as this is set the rubber core can be deflated and removed for use elsewhere. It is stated that 6 in. pipes have been made on this plan out of hydraulic lime and sand, at a cost of about 22 cents per yard.

ENGINEERING NOTES.

The Railroad Gazette estimates that to put the railway rolling stock of the United States on a normal basis of efficiency, orders this year will have to be given to the shops and factories for 2,342 locomotives, 97,246 freight cars and 5,400 passenger cars. During the past nine months of the current year locomotives to the number of 771 have been ordered, freight cars 27,700, and 179 passenger cars. Only 77 railway companies have ordered new engines, and the freight car orders have been placed by about the same number of companies. About one-third the number of locomotives have been ordered that should be built to thoroughly equip the roads. The freight cars which have been ordered are less than one-third the number which estimates designate as the requirement necessary to bring equipment up to a proper standard. Orders are about one-third the number built in 1890. The Lumberman adds that "thus it can be seen that the prospects for work in the car factories for the remainder of the year are good. The activity already developed is not likely to flag for months, but, rather, is likely to increase."

Some interesting experiments to ascertain the influence of cold upon the bending properties of wrought iron, Siemens Martin open-hearth steel, Thomas steel, spring and cast steel, have been made by Prof. M. Rudeloff, director of the imperial German testing station, says The Engineer. The samples were rounded off on the edges; the tests were made in a press. Cooling down to −20° C. exercised but little influence upon the flexibility of the different materials tested. Only in the case of spring steel and forged iron a reduction of the bending angle was observed, from 91° to 84° with the former and from 159° to 139° with the latter, while the other samples could be bent together at −20° C. as well as at ordinary room temperature, so that the two shanks covered each other, equaling a bending angle of 180°. The flexibility was in some cases at −20° C. even higher than at ordinary temperature, only in the case of Siemens-Martin and Thomas steel it declined from 100 to 80. The samples showed at the bending place no change in the material that might have been caused by the cooling down to −20° C. A cooling to −80° C. had likewise very little influence upon the flexibility of soft rivet iron and rolled puddled iron, but the flexibility of the other materials suffered by the lower temperature, especially cast and spring steel.

The degree of accuracy attainable in modern naval gunnery in actual warfare is something yet to be determined. With the exception of the battle of the Yalu during the Chino-Japanese war, there had been no opportunity for finding out what might be accomplished at long range by a modern gun, mounted on so unstable a platform as the deck of a rolling vessel; and the value of the Yalu fight as an object lesson in this respect was impaired by the relatively unskilled character of the gunners, says Cassier's Magazine. Certain it is that while death and destruction were meted out all around in that encounter, an enormous amount of ammunition was used up in the work. The bombardment of Alexandria by the British fleet in the early eighties afforded none of the conditions of a sea fight, since the vessels were at anchor in practically smooth water and their target was certainly immovable enough; and even there the expenditure of powder and shell was out of all proportion to the damage inflicted. The point has recently been made, however, that, after all, it is astonishing that a ship is ever struck by a projectile from a gun, and that there is probably more luck than cunning in the art of modern naval warfare. In a lecture at the United States Naval War College at Newport, Prof. Alger, a short time ago, stated, for example, that at a convenient fighting distance, say two thousand yards, a modern battleship, like the Indiana of the United States navy, appears to be of the same size as a picture of her, eight-tenths of an inch long, held at the point of clear vision, about 14 in. from the eye, while the outlines of the real ship will be much less clear and distinct than those of the picture. The height would, of course, appear to be still less, so that the difficulty of hitting such a target, even with the ship at rest and the gun in a fort, instead of both moving more or less rapidly, can be appreciated at least to some extent. The element of luck truly must enter largely into effective fire under such conditions.

Capt. G. A. Chaddock, F.R.G.S., a Liverpool navigator of thirty years' experience in both steam and sailing craft, has invented an appliance which ought to be of immense value to shipowners and their crews all the world over in saving both life and property. The present wooden hatches, laid on from above, are easily forced up by the inrush of water consequent upon a hole being knocked in the bottom of a vessel, the results being that she rapidly tips and sinks. The telescopic iron hatches, which constitute Capt. Chaddock's invention, are so arranged that the pressure of water from below would, in such a contingency, bind them more tightly in their places, precluding the possibility of the water rising above the first deck, which forms a platform or horizontal bulkhead, preventing the ship from sinking and water from reaching the cargo from above. The improvements give more effective ventilation to prevent cargo heating and sweating, and are also capable of being hermetically sealed, so as to neutralize fire, and, generally speaking, watertight compartments are doubled, the consequent seaworthiness of a vessel being vastly increased. Besides these essential advantages there are many others, as, for instance, more speedy manipulation and no risk of injury by careless handling. Bad smells from cargo do not reach the passengers. The vessel would be a salvage appliance in herself in case of stranding, and last, but not least, the hatches are particularly suitable for deep water ballast tanks. The practical effect of Capt. Chaddock's improved hatches will be to multiply the watertight divisions of a ship in proportion as the number of decks are to bulkheads. Thus a ship with eight bulkheads and three decks would at present have only nine watertight compartments with wooden hatches, but with the improved hatches and watertight decks the same ship would have twenty-five compartments, an increase of sixteen extra compartments. Capt. Chaddock's improvements have been submitted to the leading shipowners, underwriters, marine engineers, and other practical men, both in Europe and the United States, and they have spoken of them in the highest terms.

MISCELLANEOUS NOTES.

That galvanized sheets which are made of steel with the oxide formed in rolling removed, and then coated with spelter, are not more generally used in boiler or tank works is because the advantages they possess are not fully understood, says The Iron and Coal Trades Review. It is, however, well for boiler makers to remember that the action of moisture, especially when impregnated with sulphur arising from soft coal, has a destructive influence on steel plates, rusting them rapidly, particularly in the lighter gages. This may be delayed by frequent painting or varnishing. A coating of spelter makes steel sheets impervious to moisture, and therefore the life of the metal is preserved almost indefinitely, especially where it may be painted with the ordinary preservatives from time to time.

The ventilation of the Metropolitan Railway, of London, has at various times given rise to a considerable amount of well grounded complaint. It is, however, a matter which, in some respects, has been the cause of needless alarm. Needless because, although the ventilation on some parts of the line is unquestionably bad, yet it has been proved that the atmosphere does not contain elements of positive danger. At the best, however, this atmosphere is, as regards personal comfort, most objectionable, although it is not so inimical to health as is generally supposed. This is evidenced by the healthy condition of those employes of the company who are obliged to spend a considerable portion of their time on the underground line. That this atmosphere does affect some persons is not to be denied, but that it is not absolutely dangerous to health is shown by the fact that one of the Metropolitan Company's servants has worked for twenty years on the line at Gower Street without detriment to his health, while another, who has spent twenty-five years in a similarly circumstanced station, is as healthy as can be desired.

Owing to transport difficulties, and also to the sluggishness and poverty of the rural population of certain districts of the Austrian empire, some peculiar methods of trading in salt have survived in Galicia, for instance, says the Trade Journals Review. For the purpose of easy transport, and in order to facilitate the retail trade, the salt is supplied in the compressed state, and the government salines of Ischl are now introducing a briquette press, invented by Philip Mayer, which turns out 1,000 bricks of salt of 0·6 kg. (1·3 lb.) each per hour. The moulds are mounted in three or four groups of six or more on a revolving table. Around this table are arranged the appliances for weighing, for filling and emptying the moulds, and the press. The apparatus requires three attendants. One man takes charge of the weighing; the second makes the brick by manipulating two levers; the third removes the finished brick. With the first machine of this kind, each operation took 17 seconds, that is to say, one set of salt cakes was delivered after that period. But larger machines have already been ordered by the Netherlands, for their East Indian colonies. In these machines up to 16 moulds are united in one group, so that 16 bricks are delivered simultaneously. Each brick is subdivided and can easily be broken into four parts, and weight and price are stamped into each brick.

As the question of good joints for conduit pipes is one of considerable interest, the Nouvelles Annales de Construction draws attention to the device, first adopted about five years ago at Elberfeld in the Wupper valley, by the well known hydraulic engineer of Frankfort-on-the-Main, J. Lindley. At Elberfeld the conduits lie in an exceedingly permeable soil. The joints have answered perfectly, and they are made easily and rapidly; the materials are, perhaps, a little expensive. The joint in question has been used with pipes widening out at one extremity in the usual fashion. The two pipes are placed in position, a tarred cord is pressed into the recess, and a little clay funnel is made on the outside, through which the mixture is poured into the ring-shaped recess between the two pipe ends, which is closed by a flat rubber washer, well greased on the one side, and held in position by a steel collar. The mixture consists of two parts, by weight, of tar and one of asphalt. It hardens within less than a minute, when the rubber washer and the clay are removed. The joint is now perfect, and the canal need no longer be kept dry, so that the operations are much more expeditious than with cement. As regards expense, a pipe a foot in diameter would require about 4 lb. of mixture, ½ lb. of cord, and the operation would cost a little less than sixpence. A much more exhaustive article on pipe joints, from which the Nouvelles Annales possibly drew their information, is published in the Gesundheits Ingenieur by Unna.

The following methods are recommended for the detection of artificial silk. Mr. P. Truchot, in the Annales de Chimie Analytique, says that in burning no acid vapors are evolved, nor is the odor of burned horn noticeable. Schweitzer's reagent largely swells both kinds of silk before they pass over into solution; an addition of water or hydrochloric acid precipitates the artificial silk as a white, flaky cellulose. When dissolved in pure sulphuric acid (66° Bé.) artificial silk forms a deep yellow sirupy fluid, which is colored dark blue by the addition of a solution of diphenilamine sulphate. The presence of artificial silk may also be detected direct, without solution, by dipping a small clipping of the fabric to be examined into a solution of diphenilamine sulphate, whereby every thread of the artificial silk is tinged dark blue, while natural silk remains entirely unaffected. Without resorting to chemical methods, a very simple way of recognizing artificial silk is given in the Dry Goods Chronicle, and one which ought to be invaluable to buyers of dress goods. A wood pulp silk is now used to a large extent in foreign made fancy goods to give a brighter effect than can be imparted to the fabric by the use of natural silk. The test is to unravel the threads of the fabric and put the silk strands into the mouth and masticate it vigorously. Artificial silk readily dissolves under this operation and breaks into minute particles, and when pulled between the fingers shows no thread, but a mass of cellulose or pulp. Natural silk, no matter how thoroughly it is masticated, will retain its fibrous strength. The artificial silk offers no resistance to the teeth, which readily go through it, whereas natural silk does. It is sufficient to moisten the thread on the tongue and then submit it to a pull between the fingers. Natural silk will resist a strong pull, wet or dry.

SELECTED FORMULÆ.

Picture Transferrer.—A very weak solution of soft soap and pearlashes is used to transfer recent prints, such as illustrations from papers, etc., to unglazed paper. Such a solution as—

Soft soap	½ oz.
Pearlash	2 dr.
Distilled water	16 fl. oz.

The print is laid upon a flat surface, such as a drawing board, and moistened with the liquid. The paper on which the reproduction is required is laid over this, and then a sheet of thicker paper placed on the top, and the whole rubbed evenly and hard with a blunt instrument, such as the bowl of a spoon, until the desired depth of color in the transfer is obtained. Another and more artistic process is to cover the print with a transparent sheet of material coated with wax, to trace out the pictures with a point, and to take rubbings of the same after powdering with plumbago.—Brit. and Col. Drug.

Transparent Photographic Prints.—The Photographic Times gives this method: If on albumen paper, soak the print overnight in a mixture of eight ounces of castor oil and one ounce of Canada balsam. Plain paper requires a much shorter time. When the print is thoroughly soaked, take it from the oil, drain well and lay it on the glass, face downward, and squeeze till all is driven out and the print adheres. If a curved glass is used, prepare a squeegee with edge parallel with the curvature of the glass. It will take several hours before the print is dry enough to apply color to it.

(2) Fix a paper photograph upon a cushion shaped glass with transparent cement; when dry, rub away two-thirds of the thickness of the photograph with sand paper. The thin film is then rendered transparent by soaking it in melted paraffin wax, after which transparent colors are applied, which appear softened down when looked at from the front. The background and heavier portions are then painted in body color upon the face of another cushion-shaped piece of glass, which is afterward fixed behind the first one.

For coloring photographs, The Era Formulary gives this process:

"Take any unmounted photographic print which it is desired to color and place it on a pane of glass, the face toward the glass. In this way the image will be seen through the back of the paper. With an ordinary pencil mark on the back of the print a rough tracing of the outlines of the photograph, marking the places where the colors must afterward be applied. When this tracing has been made, remove the photograph, lay it on blotting paper and apply the colors to the back of the print. The colors should be spread on in flat tints, it not being necessary to use demi-tints. For example, a flesh tint is put on the face and black or brown on the hair; if the picture is a landscape, the trees are colored dark green, the sky part blue. It is important to use strong colors, which will show through the paper better. After this operation is finished, and when the colors are dry, the photograph is rendered transparent as follows:

First prepare the following solution:

Benzine	10 parts.
White vaseline	1 "

The vaseline is dissolved in the liquid and then the mixture is ready for use. Then the photograph, which has been colored previously, is placed on some sheets of white paper, and the back of the picture is saturated first, pouring the solution on it and rubbing with the finger to cause the mixture to penetrate, first the color and then the paper. The print is then turned face upward, and this side is saturated in the same way. After this operation the paper becomes oily and transparent and the color begins to show through. It is left to soak thus for an hour or two, then both faces are rubbed with linen until no oily spots are seen, when the proof is placed on white paper. The operation is then completed and the proof has only to be pasted on cardboard, the same as other photographs. But, as the paper is still saturated with vaseline, water paste will not answer, and the same kind of varnish will have to be used. This process of painting, which can be used by anyone, gives very beautiful effects. Colors which are thus applied to the back of the photograph give it a tone of admirable freshness, and the vaseline mixture brings the image out. Besides, as the colors have the thickness of the paper to pass through, they are greatly softened and thus approach nature. The variations of the tints will be seen, by transparency, when looking at the picture. As to the colors, any that are at hand can be used, whether water colors or oil colors. The essential point is to choose the strongest colors, rose, green, etc., and to put on only a very thin layer, as otherwise the vaseline cannot pass through it.—Pharmaceutical Era.

Yellow Coloring for Beverages.—The coloring agents employed are fustic, saffron, turmeric, quercitron and the various aniline dyes. Here are some formulas:

(1)	Saffron	1 oz.
	Deodorized alcohol	6 fl. oz.
	Distilled water	4 "

Mix alcohol and water, and then add the saffron. Allow the mixture to stand in a warm place for several days, shaking occasionally; then filter. The tincture thus prepared has a deep orange color, and when diluted or used in small quantities gives a beautiful yellow tint to sirups, etc.

(2)	Ground fustic wood	1½ ounces.
	Deodorized alcohol	4 fl. ounces.
	Distilled water	4 "

This color may be made in the same manner as the liquid saffron, and is a fine coloring for many purposes.

(3)	Turmeric powder	2 ounces.
	Alcohol, dilute	16 "

Macerate for several days, agitating frequently, and filter. For some beverages the addition of this tincture is not to be recommended, as it possesses a very spicy taste.

The non-poisonous aniline dyes recommended for coloring confectionery, beverages, liquors, essences, etc., yellow are those known as acid yellow R and tropeolin 000 (orange I).—Pharmaceutical Era.

THE EMPEROR WILLIAM MONUMENTS AT MAGDEBURG AND COBLENZ.

THE year now drawing to a close has been signalized by two events of considerable importance. The sixtieth anniversary of the reign of Queen Victoria was celebrated in England during the summer with ceremonies befitting this extraordinary event, and about the same time Germany was making a fête day of the centennial anniversary of the birth of the great Emperor William. This occasion had a double meaning to the German race and signified not only a token of remembrance to him whom they regarded as a great and good man, but stood as well a memorial of the birth of the great German empire. It was a befitting time to raise substantial memorials, and monuments have been erected to the memory of Emperor William in all parts of Germany. Many of these monuments are large and magnificent, and we have already published quite a number of them in the pages of the SCIENTIFIC AMERICAN and SUPPLEMENT. We take pleasure in presenting to our readers two imposing monuments which have recently been dedicated to the public.

THE EMPEROR WILLIAM MONUMENT AT MAGDEBURG.

Of the two, one is at Magdeburg, the other at Coblenz. Thus each represents a different style of work, as a glance at our illustrations will prove. The Magdeburg monument, which was unveiled on August 25, was designed by Herr Rudolf Siemering and is distinguished mainly by its tasteful simplicity. It has been placed on the main square of the northern part of the city, outside the old fortifications. The site is very favorable, the background of the monument being very appropriately occupied by a fine building.

The erection of a monument to the old emperor by the city of Magdeburg was planned very soon after his death, as early as the 24th of March, 1888 (William I died on the 9th of the same month). Three months after, on the 19th of June, voluntary contributors placed in the hands of the committee formed in connection with the enterprise a sum of $50,000. Siemering was requested to hand in plans for a suitable monument. He complied, and, his design being approved of, the execution of the work was committed to his charge. The site chosen was at the time as yet free from buildings, but it was hoped that before the completion of the monument suitable surroundings would have grown up. And this hope we see was realized.

As regards the monument itself, certainly its most striking element is simplicity. The absence of a great number of details of secondary or, at any rate, only ornamental importance results in a concentration of the attention of the beholder on the main figure, Emperor William the First, arrayed in his uniform and mounted on a noble steed. The arms of the German empire, those of the city of Magdeburg, and a simple dedication on each side, are the only decorations which the artist has given to the pedestal.

The dimensions of the various parts we extract from Ueber Land und Meer, to which publication we are also indebted for our cuts. The length of the pedestal, measured at the height of the inscription, is 13 feet, the breadth at the same height is 4 feet 6 inches. The ascending stairs, which form a base, are 32 feet by 20. The point of the emperor's helmet is 32 feet above the level of the street; the statue, with the horse, measures 15 feet in height.

The effect of the whole is completed by a relief which runs across from left to right at the back of the monument. This relief has an interesting history. It was modeled by the artist in 1870 at the time of the calling out of the army, and produced quite a sensation at the time. But it was never until the present occasion worked out in stone. There it now stands, reminding the nation of one of the greatest events in her history during the reign of the great emperor.

The statue was cast by the Lauchhammer Iron Foundry, of an alloy of aluminum, tin and copper. The granite was shaped by the firm Kessel & Röhl, of Berlin, the stone being the brownish red Wanewyk granite from Sweden. The platform surrounding the pedestal is inlaid with a mosaic by Rudolf Leistner.

To turn to the Coblenz monument, we find in it altogether another style of work. A massive architectural pedestal raises the figures aloft, and as the monument stands on the peninsula formed by the junction of the Rhine and the Moselle, a very fine distant view across the water is obtained from several points. In details also this monument differs considerably from the one at Magdeburg. The figures, of which there are two, are placed immediately on the architectural base. This latter is a large square structure, to which flights of steps ascend from all sides. It is made of large stones and consists of two parts, one a raised platform, around the sides of which runs the inscription, "Wilhelm dem Grossen;" the other, the pedestal proper, consisting of a number of low and massive columns. Those which form the corners are more massive yet than the others and bear decorative shields. Below the inscription "Kaiser Wilhelm dem Grossen" is a relief representing an eagle spreading his wings in protection over a crowd of men fleeing from a hydra.

The statues stand on a level 94 feet above the river, and the equestrian statue of the emperor is 45 feet high. The other, a winged allegorical figure, bearing the laurel wreathed imperial crown, is 30 feet high.

The statues were cast by A. Hinkleben, of Brunswick, according to a design by Hundrieser & Schmitz. The stone is partly granite from the Black Forest and partly basalt. The total expenses of the erection of the monument, amounting to $475,000, were covered by the surplus of interest of the Landes Bank.

These two monuments are a fitting tribute paid by two important German cities to the memory of the emperor under whose rule the ancient realm regained by the sword its former power, to settle into a time of peace and prosperity.

RELIEFS ON THE EMPEROR WILLIAM MONUMENT.

TREATMENT OF LOW GRADE ORES BY CONCENTRATION.

THE above is the title of a paper read by E. B. Kirby, of Denver, Col., at the recent meeting of the International Gold Mining Convention in that city. The following is a condensation of the article:

It is well understood that most ores of the precious metals are composed of rock with mineral crystals distributed through it. These minerals present in any particular ore may comprise one of several out of a large list. As a matter of fact, there are four which are so common and prevail so universally in mining districts that few mills have to deal with any others. These minerals named in order of frequency with which they occur are pyrite (iron sulphide), blende (zinc sulphide), galena (lead sulphide), and chalcopyrite (copper and iron sulphide).

Each of these minerals may contain both gold and silver, but pyrite and chalcopyrite are the common carriers of gold, while galena and blende have a special affinity for silver. It is also well known that in unoxidized or sulphide ores the gold and silver contents are not distributed uniformly through the mass, but are generally confined to these mineral crystals. By crushing the ore and separating out the valuable crystals from the waste material or gangue its value is concentrated into their small bulk. This will bear the expense of shipping and smelting or of treatment by the more expensive processes.

Concentration milling is, therefore, the most important of all processes applied to low grade gold and silver ores. It is of the same fundamental importance here as in the field of simple lead, copper and zinc ores. It is of more general application than any other process, and by one simple treatment, performed at the mine, it gets rid of the mass of valueless gangue. The cost ranges from 20 cents to \$1.50 per ton, according to the capacity of the mill and the system employed. It is, therefore, the cheapest of all processes, with the single exception of free gold stamp amalgamation, which costs from 35 cents to \$1.25 per ton and produces a product in the form of bullion which requires no further treatment. The more expensive processes of pan amalgamation, barrel chlorination, cyanide and smelting entail an expense per ton of ore which greatly exceeds that of concentration. The latter will always maintain its superiority in cheapness, and also in its range of application. The other processes find their special field in the treatment of concentrates, or of high grade ore, or of ores which are of exceptional character, and do not yield their values to the simple operation of concentration or free milling. The gold ores of Mercur, or of Cripple Creek, or the quartzite ores of the Black Hills, together with the oxidized lead and heavy sulphide ores of various districts, are illustrations of the latter class.

Before mining men it is unnecessary to dwell upon the extent of our resources in low grade ores of gold and silver. All realize the opportunities they present for the future application of capital. The majority of these ores can be utilized only by concentration milling. As costs lower and extraction improves they will be gradually brought into use. But the extreme economies in mining and milling can only be secured by operating with modern skill upon a very large scale, and this requires a large capital. Hence, these resources are not waiting for the invention of some new and magic process. The process is already at hand. According to the skill and capital with which it is applied, it can now be made to yield almost any results within reason.

The more recent processes, like barrel chlorination and cyanide, together with their various modifications, have developed so rapidly within a few years that they have attracted great attention. Much has been written and published about them, and the mining world is already well informed upon the latest methods, results and costs of each one. Concentration, although of more importance and more widely applied, has not progressed in such a startling way. The general mining public have, therefore, had less information upon its present development.

In crushing ore for the process, it must be broken fine enough to free the mineral crystals from the gangue. For most ores the size necessary for this purpose is quite small, so that the crushing unavoidably produces a large percentage of flour or slime. Moreover, this slime generally contains the richest minerals present in the ore, because these are more soft and pliable than the quartz. Slime requires the most elaborate and expensive machinery for its treatment. It has to be handled more slowly and is subject to heavier losses than grains of larger size.

The problem always presented, therefore, is how to crush so as to liberate all the mineral, but at the same time to avoid a large slime production.

These objects are secured by making use of one or both of the two following methods:

1. The ore is subjected to an operation of part crushing, which is repeated several times. After each operation the grains which are small enough are sifted out.

2. The ore is crushed to a size somewhat larger than that necessary to liberate all the included material, and the oversized grains are then subjected to a rough concentration on jigs. This takes out the liberated mineral and thus promptly withdraws most of the values from the danger of further crushing. The impoverished grains are then crushed again to the proper size and concentrated.

Each of these methods calls for a more complicated and expensive crushing plant. How far their advantages outweigh the cheapness and simplicity of crushing to the final size in a single operation is always a question for calculation and experienced judgment. In general it is to be noted that American mills differ from those of Europe in showing a marked preference for the more simple plan.

The grains of the crushed mass range in size from the crushing limit of, say, $\frac{1}{4}$ in. diameter down to microscopic flour. They possess two properties, and only two, upon which it is possible to operate. These properties are size and specific gravity. It is, therefore, necessary to operate first on one and then on the other. Strictly speaking, it is impossible to effect any separation by acting upon both at the same time. For instance, a grain of pyrites is heavier than quartz, if the two grains are of the same size, and it will therefore fall more quickly in water. But it is not heavier than a very large quartz grain, and, if two such unequal grains fall together, the quartz will fall more rapidly.

Hence, in order to make a separation, it is always necessary to perform two distinct operations in succes-

INAUGURATION OF THE EMPEROR WILLIAM MONUMENT AT COBLENZ.

sion upon the crushed grains. The order adopted is not an essential matter, and concentration is therefore effected either by sizing and then sorting or, on the other hand, by first sorting and then sizing. According to one plan, the grains are first divided into a number of different sizes. Each size is then subjected to the sorting effect of a fall in water, which separates all the quick falling mineral grains from the slow falling rock.

By the reverse method the grains are first sorted into a number of classes, each of which includes those grains which fall in water at the same velocity. It takes a large grain of the light quartz to fall at the same speed as a small grain of the heavy pyrites; so that in each equal falling class the quartz grains are all of larger size than the pyrites grains. The subsequent operation of sizing, performed on each class, separates the large grains from the small ones and completes the concentration.

These well known principles are simple enough and the two operations required do not seem difficult. Nevertheless, there is a great variety in the machinery and apparatus for performing each one. In practice the work of a concentrating mill is rarely confined to these two simple operations. It is complicated in various ways. If one operation is not done well, those which follow it suffer. Imperfect work, therefore, often makes it necessary to repeat the series. There is a large class of grains in which the crushing has failed to break the mineral from the rock. The grain, therefore, has an intermediate specific gravity and does not find its proper place. Other grains have peculiar shapes, which alter their rate of fall in water. Such middling products must be provided for and require special treatment. Most ores are more difficult than the simple case of quartz and pyrites. The differences in specific gravity are slight, or it may be necessary to separate several minerals not only from the gangue, but also from each other.

For the operation of sizing grains, screens are naturally employed whenever it is possible to use them. In practice screens do not work well on grains smaller than coarse sand. Inclined plane sizing machines are, therefore, used for all fine material.

Machines of this class have an inclined plane over which a very thin sheet or film of water is made to flow. This sheet of water is only one-twentieth of an inch thick and moves most rapidly at its upper surface. At the bottom, where it is in contact with the inclined plane, the water flows more slowly on account of friction. When grains of different size are treated, the large grains, resting on the inclined plane, reach into the quick moving part of the stream and are rolled down the slope. The small grains lying in the slow moving region, close to the bottom, roll more slowly or not at all. The small grains which thus remain upon the inclined surface are either allowed to accumulate, as in hand or intermittent buddles of all kinds, or they are removed automatically by various methods. In one class of machines percussion or jerking movements are applied to the table. They cause the deposited grains to crawl out of the way and thus discharge themselves. In revolving buddle and belt machines the surface itself moves slowly from under the depositing current and thus carries its deposit to the discharging point.

All these appliances, when used according to the scientific principles of concentration, are sizing machines, and the grains which deposit upon them do so because of their smaller size, and not because of their greater specific gravity. In order to secure good results from them it is, therefore, necessary to treat only grains which are equal in falling and in which the mineral grains are consequently all smaller than those of the rock. It follows that they cannot do good work unless the preliminary sorting has been well done.

The second fundamental operation of sorting is performed either by hydraulic classifiers or by jigs. There are two leading varieties of hydraulic classifiers. Those of one kind sort by allowing the grains to fall in a deep on-flowing stream of water. This deposits the quick-falling grains near its head and carries the slow-settling grains further on. Each class of grains is, therefore, deposited at a different point. Another type of classifiers subjects the grains to a series of rising currents of different velocity. Each of these is adjusted so that grains of a certain falling speed will sink through it while the others are carried on.

The jig, though a simple machine, is remarkably efficient; and, unlike classifiers, it does its work very perfectly. It is most remarkable for the fact that, like a jack knife, it can be applied to a variety of uses. It will either sort or size, according to the way it is used. Moreover, it can be made to do good sorting on grains which vary greatly in size. The complex laws of jig action have been the subject of elaborate scientific investigations which are not within the province of the limits of this paper. The greatest American improvements in concentration, however, are based upon certain methods of utilizing jigs. It is, therefore, necessary to refer briefly to the main features of their action.

Mining men are familiar enough with the machine itself, which, in its present form, is very simple. Two to four flat stationary sieves, arranged in a row, are partly submerged in a box or tank of water. The stream which conveys the grains to be jigged is led upon the first sieve of the series and flows along the row to the point of discharge. By means of large pistons applied to the water in the box, it is caused to pulsate or rise up and down in rapid succession through the apertures of the sieves. At each pulsation the entire mass of grains resting upon the sieve is suddenly lifted up a short distance by the water, and is then allowed to fall back upon the sieve. The more rapid falling grains gain a little upon the others during each fall, and finally reach the bottom of the mass. Grains too large to pass the sieve accumulate upon it and are discharged by simple devices. Small grains which pass through the sieve fall into the body or "hutch" of the jig and are drawn off below as "hutchwork." The slow-falling grains accumulate at the top of the mass and are carried off by the outflowing stream. For some purposes it is necessary to have the water sink down again after each lift. The fast-falling grains are thus drawn down more rapidly by its quick suction. For other work this down suction is injurious. The machine is then so arranged that it will merely give a series of sharp lifts, after each of which the water either falls back slowly or remains stationary.

The jig is applied to three classes of work:

1. It is used to sort grains of the same size, and in this case each jig is fed with one of the sizes produced by the screening apparatus. When such equal sized grains are jigged, the quick-falling mineral grains promptly descend to the bottom of the mass.

2. It is used to size the grains of an equal falling class which are delivered to it from a hydraulic classifier. In order to accomplish this work each sieve is provided with a permanent bed or layer composed of large grains of heavy mineral. The interstices between these large grains have much the same effect as a sieve. The small or mineral grains descend through them against the rising currents and finally pass into the hutch.

In the German system of concentration the use of jigs is restricted to the two aforesaid operations. There is, however, a third way of using jigs known as the English method of jigging. This is because it was most extensively practiced in the mining districts of Great Britain and attracted attention because of the remarkable results of the old fashioned hand jig. American practice has taken up and improved this method of jigging and made it the basis for one of the most efficient modern systems of concentration.

In this method the jig is not fed with grains which have been previously either sized or sorted. On the contrary, it treats the entire mass of material just as it comes from the crushing machinery, and includes grains of all sizes and all specific gravities. A heavy bed of coarse grains is kept upon each sieve and the water pulsations are arranged so as to give a downward suction after each lift. It is found that those grains which are too large to penetrate the interstices of the bed are near enough to the same size to separate very well upon it. The sands and slimes which do enter the interstices are subjected to peculiar laws of fall and of suction which prevail in such restricted channels. The result is that the mineral grains of greatest specific gravity pass through into the hutch, while the others are driven back and carried off in the tailings. The action of currents in these interstitial spaces has a very singular effect. They lessen the influence which differences in grain size usually have upon their falling speed. In consequence it becomes possible to thus operate at once upon the specific gravity of grains which differ very greatly in size. The very finest slime, however, cannot be concentrated in this way, and must be separated and treated by the usual methods.

The hutchwork concentrates which have been made with such an apparent disregard of size are not very clean, and require another treatment in order to yield a pure product. This is done by the simple plan of repeating the same operation with some slight differences in its details. The impure hutchwork from the roughing jigs is delivered continuously to finishing jigs placed at a lower level. These complete the work and produce clean concentrates.

But one class of machinery remains for consideration, and this is important, because it has found its chief use in the stamp mills of the West. It is, therefore, the basis for what might be termed the stamp mill system of concentration. This class includes vanners, pumping tables, and shaking and jerking tables, of many designs. They are intended to treat only finely crushed material like sand and slime. They do excellent work on assorted grains. Moreover, they do not perform a single fundamental operation, like sizing or sorting. On the contrary, each machine performs two operations in succession, one of which might be termed "settling," while the other is an imperfect zigzag, generally called "washing." Machines of this class maintain a flat, shallow stream of water, which flows down an inclined surface. This stream is not a thin sheet or film, as in the zigzag machine previously described, but it is from one-half to three-fourths of an inch thick. The crushed material is generally treated as it comes from the stamps and without any preliminary sorting. As the grains settle out of the stream, they are prevented from packing and are kept in a semifluid condition by shaking, bumping or jerking movements imparted to the inclined surface. The effect is rather complicated. The quick-falling grains, whether large or small, tend to work to the bottom of the mass, while the small grains tend to sift down through the interstices of the larger ones.

There is no clear or definite separation, but as a final result most of the mineral grains sink beneath the top layer and accumulate near the bottom. This enriched bottom layer is gradually drawn out from under the settling stream. This is effected either by the gradual travel of the surface or belt, as in vanners, or by the crawling action of the grains themselves, caused by the bumps or jerks. The concentrates thus produced by this "settling" operation are impure and have to be cleansed by "washing." This is done on the same machine just before discharge, generally by a thin sheet of water applied in jets. The precise effect of this "washing" varies with the movement and the surface used, and is too complex for analysis here. In most cases it is a quick and imperfect sizing. Although each of the aforesaid operations is imperfect in itself, the two in succession effect a very satisfactory concentration upon fine crushed and unsorted grains.

When machines of this class are fed with equal falling grains produced by a hydraulic classifier, they then become very efficient sizing machines and the concentration is greatly improved. When acting upon sorted grains, the settling operation causes the small grains to work through and under the large ones. The final quick washing by a thin sheet of water upon the inclined plane of the machine is, of course, a sizing action, and in this case it is not complicated by the presence of unsorted grains. Vanners, which are the best known of these machines, have found an extensive use for treating sorted grains in complete concentrating mills.

Gold and silver stamp mills operate upon ore which contains either free gold or silver in forms which will yield to the process of amalgamation with mercury. But very few ores found at the present time are strictly free milling, and as a rule part of the values are contained in sulphide crystals. It is, therefore, generally necessary to supplement amalgamation by the concentration process.

Amalgamations require very fine crushing, and therefore furnishes material very difficult to concentrate. Moreover, there are many stamp mills which are designed solely for concentration, in which this fine crushing has been adopted because the minerals are finely disseminated through the ore. When such fine material is to be concentrated, the standard German system for treating sands and slimes, if properly designed, will generally secure the best extraction. At Western mills, however, simplicity of plant is a very important matter. The general preference is, therefore, for machines of the class just described, which have the advantage of giving good working results on unsorted or poorly sorted material.

In many cases this desire for simplicity has been carried too far. These machines save more and have greater capacity when they are fed with properly sorted grains. To introduce hydraulic classifiers in a mill causes some complications, particularly when the mill has not been built for their use. The plant also requires more attention and skill. There are few cases, however, when the increased saving will not more than offset these disadvantages. When hydraulic classifiers are adopted, it then becomes a question whether the standard German sizing machines are not best for these sorted grains. Here opinions differ. Rittinger percussion tables, belt percussion tables and revolving buddles now become rivals of the Western vanners, bumping and shaking tables. It may be well to observe that upon most sorted grains both classes of machines do good work. In treating the very finest slime, however, the inclined plane sizing machines, when properly adjusted, appear to have the advantage.

In reviewing the standard machinery and operations of the process, the Missouri and the stamp mill systems have been described. The other two are now easily understood.

The German system is the one most generally used, even in this country. In this system all large grains are first carefully sized by screens. Each of the many sizes is then sorted on a jig. The smaller grains, from sand size down, are, on the contrary, treated by reversing these operations. They are first sorted by hydraulic classifiers, and each class is then treated in a sizing machine designed for it. Those classes which include the large sands are put through jigs, which are operated as to size, instead of sorting the grains. The fine sand and slime classes are treated upon the standard inclined plane sizing machines, such as Rittinger percussion tables, continuous belt percussion tables and revolving buddles.

The German system requires a complicated plant, which has a comparatively small tonnage for the money invested. The cost per ton is also great, but against these faults it presents the advantage of effecting a closer saving than other systems. It is also preferred for difficult work; when the differences in specific gravity are slight, or when several minerals have to be separated, not only from the gangue, but also from each other.

The Lake Superior system was evolved to treat great quantities of ore with a more simple plant. The ore is crushed by steam plants, each head having a capacity of 300 tons daily. The grains, both large and small, are at once sorted into equal falling classes by hydraulic classifiers. Without entering into the peculiar details of Lake Superior jigging, it is sufficient to say that each class of large grains is put through a jig, whose principal function is sizing. This action is complicated somewhat on account of the fact that the preliminary sorting is not very perfect. The concentrates discharged from the hutches of these first jigs are not all pure. Some of the hutchwork is therefore treated again upon finishing jigs set at a lower level. The fine slime and sand classes are sized on revolving buddles, as in the German system. In some mills the hutchwork from the roughing jigs is sorted by hydraulic classifiers before it goes to the finishing jigs.

The mill of the Calumet and Hecla mine has a capacity of 6,000 tons of ore per day, and the cost is under 20 cents per ton. This system has also supplanted the German at the copper silver mines of the Anaconda Company in Montana and also at the Butte reduction works. The Anaconda concentrating plant has a capacity of 6,000 to 7,000 tons daily.

This system, together with that used in the Missouri lead and zinc regions, is specially adapted to ores which concentrate easily and do not require fine crushing. Constant improvements are being made in their efficiency, and on suitable ores they may yet rival the German system in close savings. It is impossible to discuss the numerous technical points which determine the question of choice, but it is well to call attention to the fact that the Missouri system is specially adapted to many gold and silver ores of the West. It is, therefore, sure to find a more extended use in this field. A plant of the most simple description applied to suitable ores will give satisfactory results. Through the Missouri mining districts numerous cheap but money making mills may be seen which include only a crushing plant and two to four jigs.

Irrespective of the system used, there is a radical distinction between American and European mills in the fact that the latter are intended to save all that is possible out of an ore. There is plenty of capital for elaborate and expensive plants, which will accomplish this purpose, and they are not run at the high pressure which prevails here. American mills are built for a different purpose. In our mining regions capital is scarce, while there is a superabundance of ore. The problem presented is always how to make money most rapidly out of the limited amount of capital which happens to be at hand for mill building. In general, it is most profitable to handle a large tonnage at the sacrifice of close savings, and mills are therefore arranged for this purpose. Even when designed to extract a high percentage of values, it is afterward generally found best to crowd the machinery beyond its normal capacity, at the sacrifice of its efficiency.

Generally speaking, therefore, the tailings losses of well designed American mills do not result from any lack of knowledge or skill. The principal losses occur in two ways: In the mineral crystals which remain included in the coarse grains and in the imperfect concentration of the fine sand and slimes. The first loss can only be remedied by recrushing and reconcentrating the coarse jig tailings. The second loss may be prevented by the use of more elaborate machinery for treating the fine material. Each remedy calls for more capital, and, when this is available, it is generally found better to use it for increasing the entire mill capacity, instead of perfecting these details.

In conclusion, it may be said that the selection of the

best system for any particular ore, and the question of how elaborate and perfect the mill shall be, are matters which call for careful judgment. Any error here results in a failure to secure the best paying mill for the money invested. Moreover, in no process is it so necessary to fit the mill to the ore. No two ores break alike or require the same outfit of machinery in each department of the mill. The selection and arrangement of machines and apparatus, the percentage which will be saved and technical details too numerous to mention all depend on the special character of the ore. In modern mill designs all these metallurgical questions are settled before building, and both the results and the cost of a mill may be known as accurately beforehand as in the case of any ordinary factory.—Mining and Scientific Press.

"HUMANIZED" MILK.

ITS COMPOSITION AND METHOD OF PRODUCTION, ERRORS TO BE AVOIDED, USEFUL INFORMATION ON THE VARIOUS PHASES OF AN IMPORTANT SUBJECT.

By HAROLD STACEY, Ph.G.

IN view of the fact that it has of late frequently been suggested that the pharmacist might with advantage prepare an artificial humanized milk for infants, it seems advisable to briefly review the literature on the subject and suggest working formulæ for those pharmacists who care to take up this subject.

CONSTITUENTS OF COW'S AND HUMAN MILK.

In the first place it is necessary to know the average composition of human milk and that of the cow, the latter of which is to be "humanized." The following table, based on analyses by J. Konig, shows the average composition of the two fluids:

	Human.	Cow.
Water	87·41	87·17
Casein	1·03	3·02
Albumen	1·26	0·53
Fat	3·78	3·69
Milk sugar	6·21	4·88
Ash	0·31	0·71

The table shows that in order to humanize cow's milk it is necessary to increase the amount of milk sugar, decrease that of the casein and albumen (these two bodies being usually tabulated together as "casein" or "albuminous constituents"), and at the same time maintain the amount of fat in statu quo.

THE PROCESS.

This may be accomplished in two ways, either by removing the casein by means of rennet and adding milk sugar or by diluting the milk with water and adding the requisite amount of fat and sugar to the diluted milk. The first method, while yielding a finer product, is not adapted to commercial ends, owing to the length of time necessary for preparation and to the expense attendant. The process is briefly as follows:

Take one pint of milk, from which the cream has been removed, and add sufficient rennet to precipitate the casein. Remove the curd, and in the whey dissolve 280 grains of milk sugar, and add this solution to two pints of new milk, subsequently adding the cream which had been removed. In this way a milk is obtained which has the following composition:

Water	87·17
Casein and albumen	2·37
Fat	3·69
Milk sugar	6·21
Ash	0·71

It will be noticed that this resembles very closely human milk in composition, the casein having been reduced one-third and the milk sugar increased from 4·88 to 6·21 per cent., while the amount of fat has remained unchanged. A simpler and in some ways more satisfactory method of reducing the percentage of casein is by dilution of the milk with water, the diminution in the percentage of fat being afterward made up by addition of fresh cream or butter. It is claimed that by diluting the milk with water it is altered in such a way that the casein coagulates in a similar manner to human milk, the coagulum of the latter being looser and more flocculent than that formed from cow's milk under ordinary conditions.

WORKING FORMULAS.

To reduce the content of casein in cow's milk to the same percentage as that of human milk, it is necessary to add three parts of water to every five parts of milk. The fat and milk sugar are naturally diminished, and the requisite percentage must be made up by addition of more milk sugar and fat. The latter is added either in the form of cream or butter, preferably the latter, owing to its more constant composition. It is readily emulsified by the milk. The following forms a good working formula:

New milk	2 pints.
Fresh butter	3 drachms.
Milk sugar	500 grains.
Water	19 ounces.

Dissolve the milk sugar in the water and add to the milk and butter previously emulsified. If cream be used, the following formula, given by Plague, will be found to work well:

New milk	3 ounces.
Cream	1½ ounces.
Milk sugar	1⅛ ounces.
Water	18 ounces.

Mix secundum artem.

TO MAKE UP THE DEFICIENCY IN FAT.

Soxhlet objects to the addition of fat to the diluted milk, and suggests that additional milk sugar be added to make up for the deficiency in fat. He states that milk containing an abnormal amount of fat cannot be sterilized without the fat becoming partially separated, and the state of emulsion so necessary to assimilation being disturbed. All the functions performed by fat are equally well performed by carbohydrate material, and to make up the deficiency in fat an isodynamic amount of milk sugar must be added to the diluted milk. According to Rubners, 243 parts of milk sugar are isodynamic with 100 parts of fat; consequently, a deficiency of 1·32 per cent. of fat may be made good by an addition of 3·19 per cent. of milk sugar. Soxhlet, therefore, advocates a milk preparation as follows: Prepare a solution of milk sugar in water of the strength of 12·8 per cent., and to every two parts of milk add one part of this solution. The resulting fluid will have this composition:

Water	85·30
Casein	2·37
Fat	2·46
Milk sugar	9·41
Ash	0·47

Such a milk possesses all the nutritive properties of human milk, is readily prepared and does away with all troublesome additions. Moreover, it coagulates in a very similar manner to human milk—a matter of the very greatest importance in infant feeding.

MINERAL CONSTITUENTS OF HUMANIZED MILK.

In the preparation of all of these "humanized milks," no mention has yet been made of the mineral constituents. This is of sufficient importance to warrant special attention. Human milk is alkaline to litmus, containing only one-sixth of the amount of lime present in cow's milk and only about one third of the amount of acid phosphates. It is very important to correct this excess of acidity and mineral salts in preparing humanized from cow's milk. This may be best accomplished by addition of sodium bicarbonate. This alkali is preferable to lime water, as cow's milk already contains an excess of lime salts. The amount necessary for neutralization of the excess of acid salts is six grains to the pint. This addition should be made after the process of sterilization. Dr. A. E. Wright has advocated removal of part of the excess of lime salts present in cow's milk on the ground that the coagulum formed is less dense in proportion to the diminution in lime salts present. He advocated the addition to the milk of a small amount of sodium citrate. In the proportion of one part to 200 parts of milk, he finds that sodium citrate prevents any coagulation by rennet, and the addition cannot be readily detected by the palate. A much smaller proportion is sufficient to "humanize" cow's milk.

THE OBJECTION TO STARCH.

Attention may be directed here to the fact that certain writers on this subject have advised the addition to these artificial milks of various forms of carbohydrate food, such as oatmeal flour or decoction, arrowroot, barley water, and even meat broths of various kinds. Such additions can only be deprecated, seeing that the saliva of infants does not contain any ferment capable of converting starch into sugar or other assimilable form. Milk sugar is the only carbohydrate found in the milk of any animal, and if additional carbohydrate food is needed, it can best be supplied by increasing the amount of this constituent.

CONDENSED MILK AS INFANTS' FOOD.

A word must be said as to the use of condensed milks for infants' food. For many reasons these milks are not to be recommended. The processes which they are put through in their manufacture lead to considerable alteration in the character of the fluid. The casein becomes less readily precipitable and is less readily digested. Changes also occur in the character of the albumen, which is generally coagulated; the percentage of milk sugar is somewhat reduced and the fat is thrown out of its emulsified state to a greater or less extent in various brands. As a rule a portion of the fat is removed before concentration. More important than this is the probable destruction of the natural germicidal properties of the fresh milk and of its natural ferment.

The variation in composition is well shown by comparing the results here given of analyses of various brands:

	Water.	Casein.	Fat.	Milk sugar.	Ash.
1	56·71	13·18	14·13	13·98	2·00
2	55·43	14·00	13·16	14·84	2·53
3	56·01	13·90	14·02	14·06	2·01
4	52·07	14·26	15·06	16·97	2·80
5	57·86	8·50	16·02	16·32	2·20
6	51·72	11·00	14·38	10·51	2·75

(These brands were all unsweetened.)

It is impossible, where such variations in composition exist, to give working formulæ for humanizing the commercial condensed milk.

THE QUESTION OF STERILIZATION.

Of considerable importance in connection with preparation of humanized milks is the question of sterilization. So much has been written on this subject that more than a summary of the result arrived at is unnecessary. A valuable paper on this subject is that by Dr. Albert Leeds and Prof. Conn in the report of the Dairy Commission of the State of New Jersey for 1892 on the "Preservation of Milk," to which those interested are referred. After what has been said on the subject of condensed milks, it will suffice to say that a boiling temperature for sterilizing milk is highly undesirable, and experiments have shown that the most satisfactory method of preserving such milks is by the method of Pasteurization. By keeping the temperature below 70° C. (158° F.) the natural properties of the milk are but little affected, while the above temperature or a few degrees below will suffice to kill all pathogenic organisms likely to be present in milk. Preservatives are not recommended for addition to humanized milk, and in particular the use of formaldehyde to preserve milks intended for infant use should be condemned. This agent, even in minute amounts, has a most injurious action on the mucous membranes, converting them, if the action is constant, into a substance closely resembling leather and setting up severe irritation. Given to infants in milk, its action on the coats of the stomach cannot be other than injurious, even in the minutest amounts, and when used for this purpose may possibly prove to be the forerunner of lifelong dyspepsia.—American Druggist.

PRODUCTION OF COPPER PLATE VARNISHES.

FOR copper print varnishes, which must be still stronger than lithographic varnishes, old linseed oil or preferably nut oil is used; the latter is never employed alone, but mixed with linseed oil to give it more viscosity. According to the product desired, 12 to 50 per cent. of linseed oil is added.

The process of manufacture, as it is performed up to the present day, consists in heating the oil in a vessel holding about 25 liters, until it flashes or gives off white fumes that may be ignited. The oil is allowed to burn for five minutes, the vessel removed from the fire and placed upon a pile of ashes, where burning is allowed to continue for a few minutes more. Then slices of bread are put in the oil, one after the other, and each is left in until it has become brown, but not burnt; onions are also said to be employed. In practice this operation, which seems to be necessary, although no explanation can be had for it, is designated the "degraissage" of the oil. Now the vessel is covered and allowed to cool off, and a clear greenish oil, a little thicker than linseed oil, is received.

To obtain a thick (strong) oil, the oil when still showing the necessary heat is again lighted and allowed to burn five to ten minutes, stirring repeatedly, extinguishing the flame and lighting it again, and repeating this twice, sometimes even three to four times. The cooled oil draws threads like sirup. The grade called "huile grasse" is of inferior consistency, and is only lighted three times during its preparation.

In large works, however, this mode of production is no longer in use; the degraissage with bread has been supplanted by one with nitric acid or magnesia; the latter, mostly employed in England, is carried out by adding 2 per cent. of magnesia to the oil, leaving it to boil one hour, then pouring off or allowing to cool.

The oil is gradually heated to 180° C. in a kettle containing about 200 liters and is kept at this temperature for three hours. Then 500 grammes of finely pulverized bichromate of potash are added and the temperature raised to 300° C., a rising of the oil being prevented by pouring in small quantities of cold oil. After the temperature has been increased to 315°-320° C. during half an hour, 500 grammes Paris blue are still added. Now it is allowed to cool and thus the strong varnish ("huile forte") is obtained.

To produce "huile grasse," the temperature is maintained at 300° to 305° C. for only five minutes; for "huile claire," the temperature must not exceed 255° C., at which it is kept fifteen to thirty minutes, according to the purpose desired.

Villon gives the following proportions for the preparation of a fine copper plate printing ink (Frankfort black): 1,000 parts "huile claire," 250 parts "huile forte," 500 parts lampblack, 50 parts Paris blue, 25 parts resin soap.

The Paris blue and the "huile claire" are exposed, in a kettle provided with a stirrer and a double bottom, which can be heated by steam, to a temperature of 100° C.; the latter is then increased to 150° and the resin soap added, stirring incessantly. After the cooling, the lampblack and then the "huile forte" are added in a mixing machine and finely ground in a cylinder color grinder. For a less careful manufacture a common paint mill is sufficient.

Villon, who has made numerous researches, in order to obtain a copper printing ink of a deep black without a reddish tint, and which will keep well, has finally adopted the following composition, each ingredient of which has its significance: 1,000 parts huile claire, 200 parts huile forte, 23 parts carnauba wax, 35 parts paraffine, 25 parts resin soap, 4 parts violette de Paris, 40 parts Paris blue, 100 parts noir de Liége, 50 parts blutkohle (bloodcoal), 200 parts noir de lie, 150 parts boneblack.

A good many other substances, such as Canada balsam, ceresine, asphaltum, stearic acid, ozokerite, Japanese wax, have been proposed, to impart the necessary consistency to the composition.—Translated for the SCIENTIFIC AMERICAN SUPPLEMENT from the Färben Zeitung.

THE FUTURE OF PHOTOGRAPHY IN ITS APPLICATION TO MEDICINE.

PHOTOGRAPHY has come so rapidly forward of recent years as an aid to our senses, and in materially increasing the value of our observations, that no apology is needed for pointing out briefly the advantages which the practical study of the art would afford the medical student. The extremely sensitive photographic film only illustrates, after all, how dull is the perceptive power of the eye, and how far short of perfection it falls, considered in the light of an optical instrument. In recommending the student to practice photography we do not do so with any wish to burden him with another subject in his already crowded curriculum. We rather enjoin him to acquire a practical knowledge of photography because it tends to sharpen his powers of observation, to lead him to make faithful records, and to cultivate in him the artistic method. Indeed, we suggest it as a pleasant, instructive and recreative pursuit, and in these days of dry and rapid plates and of cheap yet good apparatus there is nothing so simple as taking a photograph and taking it well. Then, again, the student's recently acquired or freshened knowledge of chemistry will in no small measure enable him to obtain good results. At most medical schools now dark rooms are provided and other facilities afforded for taking photographs, since a knowledge of practical photography is found to be extremely useful in the dissecting room, in the post mortem room, in the ward, and in the operating theater, while the capacity to take a micro-photograph is essential in the practical study of bacteriology and physiology. Even in these applications photography may be pursued as a hobby, but what a useful hobby! It is but a simple step from the photograph to the block picture used for illustrating published communications, and in describing cases of surgical or of general medical interest photography again and again proves an invaluable aid.

We go a step farther than this, because the extreme sensitiveness of the photographic film has more recently laid bare certain phenomena which otherwise would probably to this date have remained unobserved. The phenomena we refer to are not interesting merely as

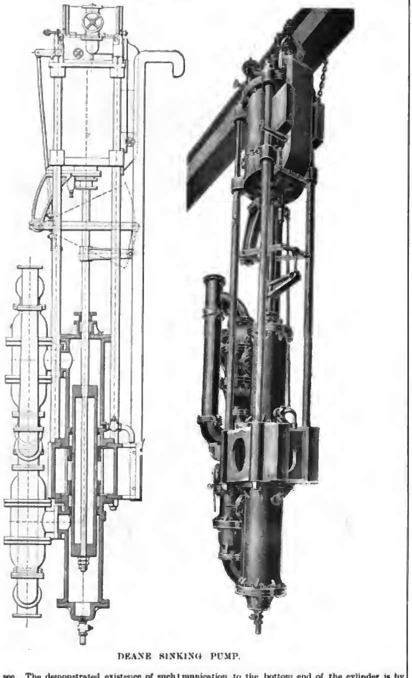
phenomena, but, as is now well known, they have led to a remarkable application of photography to the diagnosis of disease and to the discernment with more or less certainty of hidden anatomical abnormalities or even of pathological conditions. We refer to the X rays. In addition to a good sensitive plate, the student requires for this work a good induction coil and a vacuum tube, but the camera is no longer necessary. Indeed, for many purposes the sensitive plate may be dispensed with, since the rays may be made visible by means of the fluorescent screen. Examples of photographs showing the internal structure of the body, of the organs and the bones, or of hidden foreign bodies are now too familiar to need any further description. The discovery has brought to light one extremely important fact, namely, that there exist vibrations which are so rapid as to pass easily through what are otherwise opaque substances, and yet which fail to create an impression upon the optic nerve. But the sensitive plate reveals them, just as it records an infinitely greater number of stars than the eye is enabled by the best telescope to see. The demonstrated existence of such highly attenuated matter must have a profound influence upon our preconceived ideas of the nature of that mysterious thing, the elementary substance, or matter. Further, it has recently been shown that light or, at any rate, vibrations similar to it, are emitted by almost all substances. Perhaps the most remarkable example of this kind is afforded by uranium and its salts, which emit a peculiar kind of light which is dark to the eye, but which very distinctly affects the photographic plate. And, strangest thing of all, this property appears to be inexhaustible. Moreover, the radiations so obtained appear to be like the X rays, able to permeate such ordinary opaque substances as black paper, celluloid, etc.

Another most promising development in photography, and one which will probably have an important bearing on medicine, is the recently announced discovery of a process by which the objects photographed may be displayed in all the variety of their natural colors. It is quite evident that when the particulars of this process are made known, an additional means of great importance and value will be at the disposal of surgeons and physicians for making more exact pictorial records of surgical and anatomical cases and morbid specimens.—Lancet.

A LARGE SINKING PUMP.

The accompanying illustrations represent a large sinking pump recently constructed by the Pulsometer Engineering Company, Limited, of Nine Elms Ironworks, London, for a mine abroad. It is on the well known Deane system, with some modifications in the details of the valve gear to suit the purpose in view.

The steam cylinder is 36 in. diameter, and has a stroke of 36 in. The pump, which is double acting, is of the plunger pattern, and is outside packed. It is 11 in. diameter by 36 in. stroke. The valve boxes, which are provided with hand doors, are made separately, and are fitted with multiple valves. The valves of the cylinder are placed above, and form part of the top cover, in place of on the side, as is the usual practice. Communication to the bottom end of the cylinder is by means of a separate casting, as shown by the cuts, and, in the event of breakage, the parts, being separate, are easily replaced. The valves are worked by the simple arrangement of rod and lever as shown. The pump barrels are held together by the center casting, to which the rods for hanging the whole pump and attachments are also fixed, the rods going up and through bosses on the cylinder and above to the slinging links and eyes. The pump boxes are fitted with gun metal grids, on which work the extra thick rubber valves with plates and buffers on the top to lessen shock. The sinking operations are much simplified by the sliding suction pipe supplied with the pump, and being partly constructed of the Pulsometer Engineering Company's union pipe, is light and strong, and well suited for sinking purposes. The total height of lift is 400 ft.—The Engineer.



DEANE SINKING PUMP.

The first notice of the use of coal is in the records of the Abbey of Peterborough, in the year 850 A. D., which mention an item of 12 carloads of "fossil fuel."

FIVE THOUSAND CANDLE POWER "EMERGENCY" LIGHT.

The "Wells light" has now become so common, and proved so satisfactory, that surprise may be expressed at its makers bringing out another high candle power oil light working on a different principle. The new light, however, which we illustrate above, is not intended to replace the older one, but for use in circumstances where the 8 or 10 minutes needed for heating the vaporizer cannot be spared, as at fires, breakdowns, etc., where every minute of time becomes of serious import. The new lamp is a spray, and not a vapor lamp, and might accordingly be justly considered as

Fig. 1.

Fig. 2.

THE WELLS "EMERGENCY" LIGHT.

a case of atavism, as the first of all the high power oil lights was worked on this principle. As then constructed, however, the power required to produce the spray was considerable, while as now made by Messrs. A. C. Wells & Company, engineers, London and Manchester, a boy can easily maintain one of the lights in full activity. As shown in Fig. 1, the lamp consists of a reservoir containing oil, and fitted with an air pump, by means of which a pressure is maintained in the space above the oil. This pressure is then utilized to force the oil up to the burner in the usual way. At the same time, however, a second pipe coming from the top of the reservoir leads air to the sprayer, which completely breaks up and shatters the oil as it flows from the burner. A pilot light fitted with a wick is kept constantly burning, and immediately the cock shown on the standard is turned, the flame starts into full activity. Closing the cock puts out the flame instantly, so that the lamp can be used very conveniently for signaling purposes. The standard, with its oil and air tubes, can be completely detached from the air reservoir, the two tubes aforesaid passing into this reservoir through glands, as shown in the figure, which, on replacing the apparatus, only require tightening up for the lamp to be ready for use. The construction of the burner is shown in Fig. 2, which also exhibits clearly the position of the pilot light. The reservoir of the latter can be filled from the main one by opening the small valve shown at the back of the spray producer.—Engineering.

ELECTRIC CABS IN LONDON.

THE London Electrical Cab Company, some weeks ago, began to run fifteen electric cabs supplied by accumulators. We borrow an account of the arrange-

FIG. 1.—THE LONDON ELECTRIC CAB.

FIG. 2.—INSTALLATION OF THE MACHINES FOR CHARGING.

ments adopted from our contemporary The Electrical Review.

The vehicle, which is represented in Fig. 1, has the exact form of a coupe. The interior is tapestried, and at the side there are windows that can be opened and others that are fixed. The coachman sits in front. The battery employed consists of 40 accumulators of a capacity of 170 amperes hour with a discharge of 30 amperes. They are mounted in a box placed upon a support, which is suspended by means of springs beneath the cab. A 3 horse power Johnson-Lundell electric motor, with a doubly wound inductor and armature, is fixed to a box in the rear and actuates a transmission shaft through a train of gear wheels. This shaft is divided into two parts, each of which, through a chain, sets in motion one of the two hind wheels. The windings and the fields may in the first place be coupled in tension with a feeble resistance. This resistance may afterward be removed and the cab run at a speed of 2¾ miles an hour. With the armatures parallel and the fields in tension, 6½ miles an hour may be made. Finally, with the two fields in quantity, the cab may be run at a speed of 9⅔ miles an hour.

The accumulators have a total weight of 1,560 pounds, and the cab complete, inclusive of passengers, weighs 3,350 pounds.

Upon the left side is placed the starting lever. As soon as this is pushed forward, the cab starts off with a speed of from one mile to nine miles an hour. It suffices to reverse the lever and place it in the center in order to stop the cab at once. If the lever is pulled back, the motion of the cab is reversed. The brake is applied to the wheel through a pressure of the right foot; the electric current is then interrupted. The steering is done solely through the maneuver of a central hand wheel placed in front of the coachman. The management of the vehicle is very easy and simple. Out of fifteen coachmen selected, twelve, after two days' practice, were capable of running the cab. While at rest, the vehicle is kept locked, and it is impossible for anyone to set it in motion. The coachman has merely to put the keys in his pocket and leave the cab to itself.

The company that has introduced these electric cabs in London has not wished to produce its own electric energy, because, in the first place, the price charged per day by the electric companies is sufficiently low, and, in the second place, because the service, upon increasing, would necessitate charging stations throughout the entire city of London.

The first charging station has been established on

FIG. 3.—CAB DEPOT.

Juxon Street, Lambeth. The alternating current is furnished by the London Electric Supply Corporation at 2,400 volts and at a frequency of 83 periods per second. There have been installed two transformers, each composed of a Thomson-Houston alternating current motor directly actuating a continuous current dynamo of 75 kilowatts of the same manufacturers.

Fig. 2 gives a general view of the installation of the two transformers. The transformation of the electric energy of high tension with alternating currents into energy of low tension with continuous currents is effected with a rendering of 86 per cent.

Fig. 3 gives a view of the cab depot and Fig. 4 a view of the charging hall. The accumulator boxes have been taken from beneath the cabs, placed upon trucks and arranged along the walls in order to be recharged. The cost of the electric energy is three cents per kilowatt hour. With a complete charge, the cab

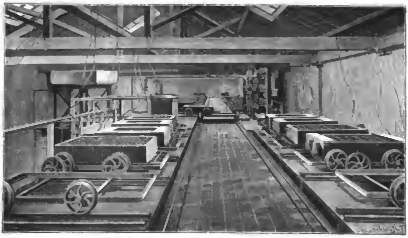


FIG. 4.—HALL IN WHICH THE ACCUMULATORS ARE CHARGED.

is capable of making a trip of 48 miles, at an expense of fifty cents.—La Nature.

THE REFRACTIVE INDEX AND REFLECTING POWER OF WATER AND ALCOHOL FOR ELECTRICAL WAVES.

THE electro-magnetic theory of light, as originally given by Maxwell, included only the optics of a single wave length, and required extension to justify and harmonize the facts of selective absorption and dispersion. This extension was made by Helmholtz. According to him, a change in the refractive index with the wave length is to be expected throughout the complete spectrum; but, beyond a certain wave length, these values approximate rapidly to a fixed limiting value, so that the index may be regarded as practically constant for longer waves. The period of this characteristic wave length is theoretically of the same magnitude as that of the slowest possible vibration of the molecule, but it is practically unknown. Yet recent researches render it probable that this close approximation to a constant limiting value is exhibited by wave lengths much smaller than all electrical waves thus far produced. It seems probable that the great change in the value of the refractive index occurs in a part of the spectrum much nearer light waves than the Hertz oscillations. Still, the researches of Gratz and Fomm (Wiedermann's Annalen, 1895) and of Drude (P. Drude, Wiedermann's Annalen, 1895) indicate a certain amount of dispersion, even for long electrical waves.

It seemed desirable, therefore, to investigate the refractive index of these substances, particularly of water and alcohol, to see if it is the same for very short electrical waves as for long ones. The work was consequently undertaken by A. D. Cole, in Prof. Warburg's laboratory, and partly under the guidance of Dr. Rubens, of the Berlin University. The paper describing the investigation is given in full in Wiedermann's Annalen der Physik und Chemie, 1896. It will scarcely suit our purpose to follow the author through the details of his work, and his minute description of the apparatus employed; we therefore simply notice that he investigates: 1. The velocity of long electrical waves in water and alcohol by the method of E. Cohn. 2. Refractive index for short electrical oscillations. 3. Reflecting power of a metal for electrical waves. 4. Reflection of electrical oscillations by liquid surfaces. The paper is illustrated by diagrams of the apparatus employed and by tables. Summarizing all the results, we find that: 1. For oscillations of 300 cm. to 600 cm. total wave length, the refractive index for water is 8·95, for alcohol 5·90. 2. For oscillations of 5 cm. wave length two Fresnel formulas give the same value for the refractive index from observations of energy reflected at 45 deg. For water this value is 8·85, for alcohol 3·2. 3. The refractive index of alcohol is decidedly greater for long than for short electrical oscillations. Clearly the research is not yet concluded. We understand, however, that the work will be resumed shortly.—Electrical Review, London.

The cylindrical car is in evidence again, this time on the electric railway at Concord, N. H. It is also a convertible car, built on the principle of a rolling top desk, the side panels sliding up grooved posts into the roof to form an open-sided summer car. In case of a rainstorm or sudden change of weather the sides can be promptly rolled down. There are transverse seats and a central gangway.

APPARATUS FOR THE STERILIZATION AND FILTRATION OF WATER.

In the matter of treating potable and industrial water, France was represented at the Brussels Exposition by the apparatus of the Delhotel system, to which Messrs. E. Fourey, Sons & Company, the manufacturers, have given the most practical form.

In all the installations in which the Delhotel & Moride filter is used for furnishing sterilized and filtered water the reagent employed is alum, which, mixed with the water in the mean proportion of four grains to the quart, frees it from its pathogenic germs. Alum not only exerts a physical action, but also destroys the vitality of the biological elements.

M. Lacour, in his remarkable researches upon the sterilization of water, has even succeeded in sterilizing filters with alum or with alcohol, which he finds preferable to heat, which, without being any surer, is more costly.

The reaction is very simple. In the presence of the carbonate of lime that almost all water contains, there forms a subsulphate of alumina insoluble in water, and sulphate of lime and sulphate of potash in infinitesimal proportion remain dissolved, and carbonic acid is disengaged. It is the subsulphate of alumina that is the sole active agent. It brings about the formation of a lake that envelops the organic and mineral substances in suspension.

In order that it may be rendered potable, water thus treated requires more than a decantation. Simple rest, even for a long time, does not suffice to free it from its mucilage, and filtration is necessary after the treatment.

There are two cases to be considered: It is possible to establish a reservoir of impure water of a determinate capacity placed above a filter which delivers the pure water to a second receptacle situated at a lower level. Into the reservoir of impure water is put the desired proportion of alum, previously dissolved in a small quantity of warm water. After this has been shaken for a few minutes, it is allowed to rest for a quarter of an hour before filtration.

Such an installation is somewhat cumbersome. Since, in reality, the chemical reaction is immediate, it is possible to establish an automatic distributer of the reagent upon the filter itself, provided that the latter be capable of freeing the water from the mucilage that envelops the micro-organisms. Now, both experiment and practice have shown that the Delhotel & Moride filter fully satisfies this condition without the gelatinous substance of the precipitate proving an obstacle to the normal operation, since the cleaning may be easily done while the apparatus is at work.

In the first description of the apparatus that we gave, an automatic distributer of the reagent was described. The one that we represent herewith is recent. In a cast iron receptacle, H, resistant to pressure and easily opened, there is a charging bucket, I, containing crystallized alum. All the impure water to be purified enters through the conduit, S. A small portion of the current passes through the cock, J, of the pipe, O, circulates over the alum and dissolves some of it. The largest discharge takes place through the cock, K, and mixes with the alumenized water in the conduit, M, ending at the filter.

The two cocks, J and K, are connected with each other through the cranks, Q, and the rod, P, which permit of regulating their respective discharges and of rendering their closing simultaneous. Besides, a cock, N, permits of perfecting the regulation of the water to be alumenized, which, through a conduit, L, is distributed by means of a perforated metallic pipe over the entire surface of the reagent and descends along the guide, G, in measure as the alum dissolves.

These cocks, having been regulated once for all, are registered. In this way there is obtained automatically, and without the necessity of any surveillance, a quantity of reagent proportional to the quantity of water to be treated.

A cock, R, interposed in the conduit, O, permits of the washing of the distributer with impure water. The distributer is charged for an operation of twenty-four hours at a minimum, and sometimes of seven days.

We shall now describe the arrangement of the Delhotel & Moride filter figured herewith.

This apparatus consists of an iron plate cylinder, A, capable of withstanding a pressure of five atmospheres, and in which there is a filtering mass, S, formed of finely pulverized silex. The water enters through the conduit, B, and the cock, 1, an annular tube, D, whence it makes its exit through four circumferential ajutages, a, having the form of an eolipyle. It traverses the sand, the collector, F, the tubulure, P, and the pipe, b, and makes its exit, filtered, through the conduit, C.

The collector consists of a cast iron disk supported by two squares riveted to the cylinder and upon which rests a perforated plate covered with fine wire gauze. Iron rings hold these different pieces by means of bolts and permit of easily changing the wire gauze. The disk, at its lower part, carries a tubulure, P, which, through friction, enters the corresponding tubulure of the conduit, b. The joint is formed with hackled flax or hemp or asbestos fiber.

In the interior of the collector there is a U-shaped piece which distributes the water introduced by the opposite current employed for the rapid cleaning, and which supports the perforated plate.

At the top of the central pipe, T, bolted to the bottom of the filter, there is mounted, through friction, a funnel, E, while below it is prolonged by a tube, of which the cock, 4, serves for the removal of the sand. By opening and closing this cock rapidly, it is possible, during the operation of the apparatus, to keep the surface of the sand clean. The water whirls rapidly upon its exit from the orifice of the ajutages of the eolipyle, and rises and drives the mud into the funnel, E, whence it flows to the exterior through the cock, 4. When it is desired to proceed with the complete cleaning of the filter, a counter current of water is employed. To this effect, the threeway cock, 1, is so maneuvered as to send the impure water into the conduit, J, and the cock, 3, for the filtered water is closed. The non-treated water enters the apparatus through the tubulure, b, flows under U, which distributes it through the collector, lifts the sand and washes it, and carries the impurities into the funnel, E.

In order to finish a washing through an opposite current, it is not necessary to wait for the water to make its exit, clear, through the cock, 4, since it can be arrested in a few minutes. The cock, 1, is then turned in such a way as to send the water upon the sand. Since at this moment the filtered water would pass in a turbid state for from one to ten minutes, the mud cock, 2, is opened so as to allow such water to flow to the sewer. When the water runs clear, this cock is closed, and the cock, 3, is opened in order that the normal operation may be resumed.

According to the pressure of the water disposable, the regulation of the opening of the cock, 1, is effected once for all, both for the sending of the water into the filter and for the washing. A graduation by index renders the registerings easy. If the filter should operate under too strong a pressure, as a consequence of a too wide an opening of this cock, the discharge would be too great, to the detriment of the clarification. As for the washing during the operation of the apparatus, too strong an opposite current might lift the sand to such a height that it would overflow into the funnel, while it should remain at a few fractions of an inch from the latter.

At the bottom of the apparatus there is a cock, protected against contact with the sand by fine wire gauze and serving for the complete discharge of the water in case the filter should have to be left for some time at rest.

Upon the cover there is a screw plug as well as a cock to allow of the exit of air.

The essential advantage of this apparatus consists in the facility with which it is possible, in less than a minute, to rid the filtering surface of its mucilaginous deposit. So it permits of successfully treating water that is very muddy or that is charged with chemical precipitates, without the necessity of having frequent recourse to cleaning by an opposite current.

No mechanical part involving any expense for manual labor or maintenance enters into the construction of this apparatus.

From the experiments made at the municipal laboratory of Paris, it results that the addition of a small quantity of sulphate of alumina to the water of the Seine (1/30,000 or 1/50,000) and a passage thereof through the filter under consideration, permit, with a

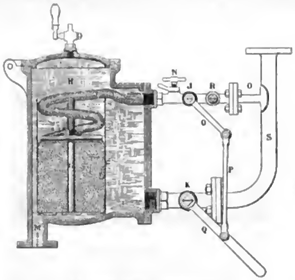

FIG. 1.—REAGENT DISTRIBUTER.

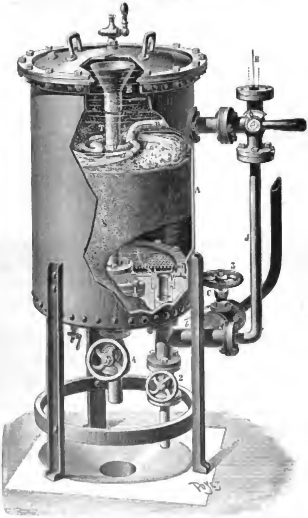

FIG. 2.—DELHOTEL & MORIDE FILTERING APPARATUS.

large discharge under a limited volume, of clarifying this water perfectly, of freeing it from the greater part of its taste and odor, of removing, at a minimum, 90 per cent. of the bacteria and of eliminating from ¼ to ⅓ per cent. of the organic matter without changing the hygrometric degree or sensibly modifying the proportion of the weights of sulphate and carbonate of lime contained in the water.

The sulphate of alumina added to the water is, moreover, entirely precipitated in the state of subsulphate, and there remains no trace of it in the purified water.—Revue Industrielle.

THE NOSE AND RESPIRATION.

IN the physical study of respiration it seems that authors formerly directed their researches only to the organs situated below the neck; in other words, all of them neglected the important study of the respiratory orifice. It seemed indifferent whether one breathed through the nose or the mouth or through both simultaneously. But within the last twenty years a new branch of medicine has been instituted, that of rhinology, the object of which is the study of affections of the nose. This specialty, the beginning of which was modest, soon established the conception that affections of the nose are not only the local diseases that they seem to be, but that they have constantly a reflex action upon the general health. In fact, children whose noses are chronically obstructed develop poorly and remain sickly. Adults who cannot breathe through the nose become asthmatic and cannot withstand prolonged exertion. Moreover, there is a notion prevalent that in order that a person may run well, the mouth must be closed and the breathing be done through the nose. Finally, we know that the victors in different sports are never those whose noses are obstructed. A series of researches recently published * permits of giving a simple explanation of all these facts, which are quite different in appearance. We have been able, in fact, to prove, by means of the processes indicated further along, that the nose is the natural organ of respiration, especially because it is so arranged as to allow of the passage, for a given time and for a given inspiratory effect, of a larger quantity of air than the mouth. In other words, the buccal orifice standing for 1, the normal nose should stand for about 1·25. It will be at once seen to what a loss of air one is exposed by an inspiration that is exclusively buccal or that is effected through a nose of reduced capacity—a case of exceedingly frequent occurrence. Such an assertion may seem paradoxical. In fact, in order to respire with full lungs, do we not open the mouth widely? and have we not thus a sensation of inhaling a larger volume of air? At this moment, the inspiration is quite ample, but such inspiration is exceptional, since it constitutes an effort that we cannot constantly repeat. On another hand, in such effort, the nose and mouth inhale conjointly. The fact must also be taken into account that, although in this effort or in yawning the mouth is opened to a maximum, the same is not the case in ordinary respiration, in which the mouth is only partly open and constitutes a narrow orifice, a transverse slit limited by the slightly parted upper and lower teeth.

An organic arrangement further explains the superiority of the nasal orifice. We know, in fact, that the two nasal fossæ are placed side by side and that their posterior orifice (which is wider than the anterior) debouches in a spacious cavity—the pharynx. The latter, from the standpoint of respiration, extends from the base of the cranium to the glottic orifice, through which the inspired air enters the chest. The accompanying diagram (Fig. 2) shows the general arrangement of these parts.

The air drawn in by thoracic dilatation passes through the nasal fossæ and enters the pharynx. Now, upon comparing the sections of the different orifices, we find that the air flows through the nasal conduits in a quantity nearly double that which is capable of passing in the same time through the glottis; whence we may conclude that such air undergoes in the pharyngeal cavity a certain compression designed to facilitate the entrance of the air into the chest. But this cavity is not inert, it possesses muscular walls which execute rhythmic motions synchronous with the respiratory ones and which were discovered twenty years ago by Garland, of Boston. These pharyngeal motions, the interpretation of which has remained obscure, seem merely designed to quicken the circulation of the air in the pharynx and to aid the thoracic effort.

It will be seen from this diagram that the pharyngeal apparatus is adapted to the nasal orifice and that the buccal orifice does not benefit by it. It is found, besides, that the nasal passage, in its entirety, proceeds by slight curves, while the buccal conduit is placed at right angles upon the glottis; and how prejudicial to the flow of a fluid an angular arrangement proves is well known. Let us add that the presence of the epiglottis constitutes also an obstacle to the buccal inspiratory current of air.

However, the preceding views, which are somewhat theoretical, required to be sanctioned by experiment.

In the first place, we may put before the reader's eyes an analysis of a series of respirations obtained by pneumographic inscription. The two tracings shown in Figs. 3 and 4 were furnished by the same subject, whose nose was nearly normal. The one to the left represents the nasal respiration of the subject (the mouth closed) and that to the right exhibits his exclusively buccal respiration (the nose obstructed).

These tracings were inscribed upon a disk having a uniform circular motion from right to left. Each respiration is figured by an angle with its apex directed toward the center. The inspiration is represented by the right side and the expiration by the left, when the apex of the angle is placed above. It will be distinctly seen that each angle is separated from the following one by a circular line, the time of repose at which the inscribing style remained immovable. The amplitude of every respiratory motion is shown by the absolute length of the tracing and its duration by the arc that it occupies.

It may be seen from an examination of these figures that the subject made in the same time a larger number of buccal than nasal inspirations—a proof that each of the former gave him less air. But we remark, too, that each of these less rich buccal inspirations is more ample and of shorter duration. We must conclude therefrom that in such cases the chest expands more widely for inhaling air, but that such amplification is of short duration, precisely on account of the effort that the subject has to make in order to expand his chest in breathing through the mouth. The upshot is that to such thoracic effort, the duration of which is short, corresponds only the introduction of a relatively small quantity of air.

Another proof of our opinion is furnished by our rhinometer, an apparatus by means of which it is possible to determine with precision the degree of the nasal respiration of a subject. We have here one of the most useful of determinations in practice, since a normal nose is rare in man, and, in order clearly to appreciate the degree of permeability of this organ, one has been content up to the present with a simple inspection. The rhinometer consists essentially of a receptacle, R, the capacity of which is known. A variable quantity of water may be introduced into this receptacle in order to diminish its capacity for air. A water level permits of knowing the quantity of water introduced. A sulphuric acid pressure gage is adapted to the receptacle, with which it is connected by a rubber tube. Three other tubes (the central one of which is provided with a mouthpiece and the two others with nosepieces) open in the apparatus.

The rhinometric test consists in causing the subject to make two inspirations—one through the mouth, with the nose closed, and the other through the two nostrils, with the mouth closed. The tubes not employed being closed, each inspiration produces in the receptacle a vacuum, the degree of which is shown by the displacement of the pressure gage column. Upon applying Mariotte's law, it is possible, through the change of pressure, to ascertain the volume of air inhaled at each inspiration. More simply, the pressure gage degree gives us the value of each orifice. To us, the nasal value of a subject is represented by the formula

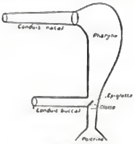

FIG. 2.

$$\frac{N}{B}$$

where N is the value of the nasal orifice and B that of the buccal. We have adopted the value B for unity because the buccal conformation is invariable, while the configuration of the nasal fossæ is rarely normal.

But, in order that the two different inspirations may be comparable, it is necessary (a) that they shall be effected with the same thoracic effort, and (b) that they shall be of equal duration.

In order to fulfill the first condition, we recommend to the subject to inspire with his maximum effort. We have thus greater chances of obtaining two efforts that are sensibly equal. The second condition is obtained through a special arrangement.

The apparatus, A, the details of which are represented in the corner of Fig. 1, consists of three electromagnets provided with hammers designed to flatten the three rubber tubes, and which are actuated by the clockwork, H, the operation of which is as follows:

Upon an ebonite disk having a uniform circular motion are fixed three concentric metallic circles interrupted according to unequal arcs. A contact, D, may be adapted to any one of these three circles, the interruptions of which are so calculated as to represent one second, half a second and three-quarters of a second. While the disk is in motion and the contact is touching the metallic circle, the current passes, the electromagnet operates, the tube is flattened and inspiration becomes impossible. When the contact touches the interruption, the current no longer passes, the tube opens, and inspiration is possible, but in a time accurately calculated.

A commutator, C, permits of causing the operation either of the middle electromagnet alone on the buccal inspiration or the two lateral electromagnets simultaneously in the binasal inspiration.

Finally, a second contact, E, in relation with the circumference of the disk, actuates, through wires, F and F', an alarm that warns the subject that he must inspire. This system produces three light bell strokes a quarter of a second before the opening of the tube. With a little practice, the subject makes the beginning of his inspiration coincide with the opening of the tube.

FIG. 1.—DR. MENDEL'S RHINOMETER.

FIG. 3.

FIG. 4.

FIG. 3.—Tracing of Nasal Inspiration (duration of the rotation of the disk, 26 seconds). I, inspiration; E, expiration; R, rest. FIG. 4.—Tracing of Buccal Inspiration (duration of the rotation of the disk, 26 seconds).

With this apparatus we have been able to determine the nasal value of a large number of subjects. There are very few that have reached 1·25, which seems to us to be the normal value (the buccal orifice standing for 1). Such value often oscillates around 1, on account of the frequent diseases of the nasal fossæ, the result of which is to diminish the permeability of the nose and thus to limit the consumption of oxygen by the individual.—Dr. Mendel, in La Nature.

* Physiologie et Pathologie de la Respiration nasale, par Dr. Mendel, 1897.

Non-Corroding Soldering Fluid.—The Iron and Coal Trades Review states that a reliable soldering fluid, free from rusting properties, may be made with four pounds of hydrochloric acid and about four pounds of ordinary zinc cuttings; if old zinc is used, a rather larger quantity will be required. It is best to add the zinc in two or three lots. When the acid is saturated—

that is, when no more zinc can be dissolved—add a small quantity of oxide to color and filter through ordinary muslin. Having filtered, add one pound of strong liquid ammonia, stir and then bottle. This preparation can be used as a soldering fluid and will not cause rust to appear on the articles on which it is used.

AN ANCIENT GREEK HEALTH RESORT.

The ancient Greeks, at all events after heroic times, were not always in the aggravatingly robust state of health that is the popular idea of their condition. Human nature is very much the same all the world over and at all times. There were many health resorts where sufferers were treated by Asklepios himself, or more frequently by his qualified assistants, i. e., the priests, and the modus operandi at these institutions formed the subject of a very interesting lecture by Miss J. E. Harrison, recently delivered before the University Extension Society, says the London Lancet. The lecturer gave an account of what was perhaps the earliest known medical school, namely, that of the centaur Chiron. Here the children of the heroes were taught simple surgery, riding, gymnastics, the rudiments of music, and, in common with the ancient Persians, to speak the truth, the last being a branch of education which has fallen into disuse among both nations. The chief subject of the lecture was, however, the shrine at Epidauros, which has recently been excavated and is in fairly perfect condition. The temple and the long corridors where the patients slept are all there, but the holy well alluded to in many inscriptions has not been found. Besides these the patients have left memorials of their cures carved upon stones, a very full one being that of a Roman gentleman, and we are able, through the courtesy of Miss Harrison in supplying us with the original Greek, to append a translation. "I, Marcus Julius Apellas, of Idrias and Mylasa, was summoned by the god, as I suffered from a variety of complaints, and especially dyspepsia; and as I was on my way through Aegina he ordered me not to worry so much about myself (μὴ πολλὰ ὀργίζεσθαι). When I arrived at the shrine, he told me to go about for two days with my head covered up, and these two days it rained. He also prescribed for me cheese and bread with celery and lettuce, to wash myself by myself—i. e., without the help of the shampooer—to drink lemonade made from citrons, to go to the fountains in the baths and rub myself against the wall, to run and do gymnastics, to walk in the portico, and to exercise on the trapeze, to rub myself in the sand and go barefoot. Also before I went into the bath I was to pour some wine into the warm water; I was to shampoo myself, but all the same I had to give an attic to the bath man. I was to sacrifice to Asklepios, Epione and the Eleusinian goddesses, and to drink milk mixed with honey. And one day when I was drinking milk alone he said, 'Put honey in your milk and you will get the bowels open.' And when I implored the god to make me well quickly so that I could get home, I had a vision in which he ordered me to rub my body all over with mustard and salt, and I seemed to go down to the springs by the shrine, and a boy went before me with a smoking censer, and the priest said to me, 'Now you are well and you must pay your fees.' So I did as the vision directed, and when I rubbed in the mustard and salt it hurt, but when I washed it off it did not hurt any more, and this happened on the ninth day after I came, and he touched me on the right hand and on the breast. And the day after, as I was sacrificing, the flame leaped up and burnt my hand so that a blister came up, but my hand soon got well. And as I stayed on there he told me that anise and oil were good for a headache. I had no headache then, but some time afterward when I had been studying I had a headache, and I used the anise and oil and the headache disappeared. He also told me to gargle my uvula with cold water (for I had consulted him on this point too), and the same treatment for the tonsils. And he told me to write all these matters down, and so, grateful and restored to health, I went away." The naiveté of this narrative is delightful, but the treatment is eminently practical. Apellas is very like the ordinary patient—the sort, we mean, who, having paid his fee, says, "Oh, by the bye, there's one thing more I want to ask you. I often have," etc.

THE LIGHT OF FIREFLIES.

In experiments on the properties of the light of fireflies, Prof. H. Muraoka used plates of copper, aluminum, zinc, and brass of equal size, separated from the photographic plates on which they were severally laid by a layer of cardboard having a cross shaped piece cut out of the center; wrapped the whole with three or four thicknesses of black paper, and exposed the bundle to the light of several hundred fireflies. His purpose, says The Popular Science Monthly, was to learn whether the light from the insects after filtration through the black paper could penetrate the metals and affect the photographic plate, and to determine the relative transparency of the substances used. To his surprise, the parts of the photographic plate under the cardboard were most darkened, while those under the cross shaped holes remained clear. The light of the insects seemed to behave very much like ordinary light, but, after "filtration," acquired properties similar to those of the Roentgen or the Becquerel fluorescent rays—properties apparently resulting from the filtration. Further, the filtered rays appeared to exert a peculiar action toward the cardboard—called by the author a suction phenomenon—similar to that of the lines of magnetic force upon iron. The properties of the filtered rays seemed to depend on the filtering substances, probably upon their thickness. They exhibited properties of reflection, but those of refraction, interference and polarization were not observed, although the author believes that they exist. Their properties, generally, appear to be between those of the ultraviolet and the Roentgen rays. The insects used in the experiments had two or three rows of luminous spots on their under-body; but the photographic plates were affected by the whole body as well as by the luminous spots, so that a complete image of the insect was formed when it was put upon the plate, the figure of the luminous part being, however, plainer than the rest.

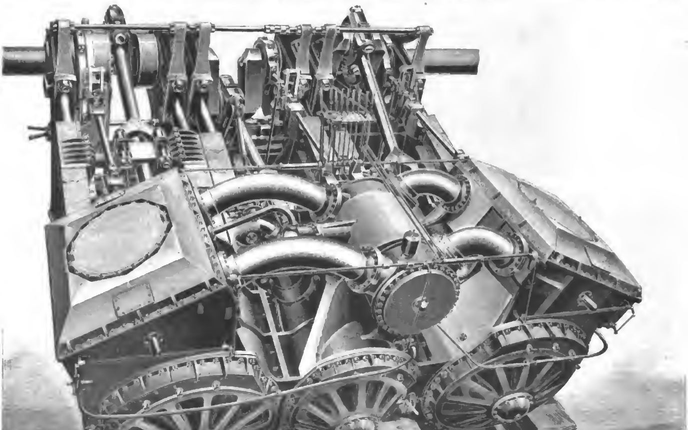
THE ISLE OF MAN STEAM PACKET STEAMER "EMPRESS QUEEN."



COMPOUND DIAGONAL ENGINES, STEAMER "EMPRESS QUEEN."

THE LARGEST AND FASTEST PADDLE STEAMER IN GREAT BRITAIN.

By A. J. SINCLAIR.

WE present engravings—an exterior and an interior view—of the new steel paddle steamer "Empress Queen," which is the largest and fastest paddle steamer in Great Britain and which has just recently been completed by the Fairfield Shipbuilding and Engineering Company, Govan, near Glasgow, to the order of the Isle of Man Steam Packet Company, Limited, Douglas, Isle of Man, for their passenger and mail service between Liverpool and Douglas (a distance of 70 nautical miles). The first vessel owned by the Isle of Man Steam Packet Company, which have now a fleet of a dozen steamers—8 paddle and 4 twin screw steamers—was built in 1830. It was of 116 tons burden and 200 indicated horse power.

It was through the kind offices of Lord Henniker (Governor of the Isle of Man) that the Steam Packet Company secured the consent of Her Majesty Queen Victoria to have the ship called after her own name. The principal dimensions of the "Empress Queen" are: Length over all 375 feet, breadth of hull 42 feet, breadth over paddle boxes 83 feet 6 inches, and moulded depth is 25½ feet. She is constructed of steel throughout and is of 2,500 gross tons. The hull is divided into several watertight compartments by means of steel transverse bulkheads, which, besides reducing the risk of foundering to a minimum, materially augment the strength of the structure, forming valuable supports and ties between the decks and framing. The decks are four in number, and are termed "lower," "main," "spar," and "promenade." The dining saloon on the lower deck accommodates 124 first class passengers, and is the handsomest saloon of its kind of any Channel steamer afloat. Ample accommodation is provided for the number stated to dine at one time, and in addition to the long tables running along the full length of the room, there are several small tables at which parties can dine. The ceiling of the saloon is in white and gold. Forward of this are the pantry, scullery and plate room.

MAIN SALOON, LOOKING FORWARD.

The pantry is furnished with all the latest appliances, including steam, hot water boiler and steam carving tables.

Another good feature is the fact that there is a saloon galley connected with the saloon pantry, where everything may be sent down without carrying the edibles through the saloon, as in the older boats. The first class smoke-room is large and agreeably arranged, the framing being in oak, the paneling in teak, and the upholstering in dark green morocco, while white and gold are the prevailing colors of the ceiling. The main saloon, which we illustrate, is paneled in mahogany, inlaid with satinwood and ebony, while the ceiling is chastely decorated in white and gold. All the upholstering is done in the finest moquette velvet, while the carpets are of the best Axminster, and form a beautiful contrast in shade with the cushions. The saloon is provided with couches, writing tables, etc., which go to make it as comfortable and complete as the most fastidious members of the travelling public could desire. To the right of the main saloon is the ladies' special saloon, which is unique in form and decoration, the latter being in satinwood, and set off in cozy alcoves by means of carved and arched columns in the same kind of wood. It is upholstered in an electric blue shade of velvet, with Axminster carpets to match. Leaving the main saloon, a descent is made by a handsome staircase to the second general saloon, which is fitted up with mahogany and satinwood panels, and upholstered in a light shade of moquette velvet, with carpets to match.

The forward part of the ship is allotted to the second class passengers. The dining saloon, forward of the machinery space on the lower deck, having bar and pantry adjoining, provides ample room for the second class passengers. On the same deck, and forward of this, is a ladies' second class saloon, supplied with every up-to-date requisite.

On the main deck above is arranged a second class shelter, which contains a bar, buffet, mail and parcel rooms. The gentlemen's sanitary appointments are of the most modern system, and are provided for first and second passengers, abaft and forward of the sponsons respectively.

On the spar deck aft, in houses, are six handsome private cabins, fitted with berths, etc., and amidships on the same deck is a cloak room, and combined bar and smoking room, while all fore and aft all available space is utilized for sitting room, there being sparred seats sufficient to seat over 600 persons.

Above this is a very spacious promenade deck extending from the fore end of the boiler room aft to the end of the first class cabin, with buoyant seats running the entire length, excepting a small portion at the after end, which is appropriated for the stowage of boats, a feature which has received special attention, so as to allow of the immediate launch of the boats if necessary.

The bridges (36 feet above the water line) that surmount the promenade deck are placed one at the foremost extremity for navigating purposes, and the other between the funnels, and extending from sponson to sponson, with captain's house under, for the better handling while docking and taking piers. From both of these bridges the bow and stern rudders are controlled by means of wheels connected with independent steam-steering gear placed below on the engine starting platform. A hand-screw steering apparatus is also placed in reserve aft in case of emergency. Docking and engine telegraphs are provided on each of the bridges. The vessel was engined by the builders.

For our engraving of the engines and for the following particulars we are indebted to London Engineer.

The "Empress Queen" is fitted with the largest and most powerful paddle engines yet built. These are of the compound diagonal surfacing condensing type, with three cylinders, viz., a high pressure cylinder in the middle and a low pressure cylinder on each side of it. The high pressure cylinder is 68 in. in diameter, and each of the low pressure cylinders is 92 in. in diameter, the length of stroke being 84 in. The lagging casing was not in place on the cylinder covers when the engines were photographed. The high pressure cylinder is fitted with a piston valve, the low pressure cylinders with flat slide valves, all controlled by the usual double eccentric link motion valve gear. The starting and reversing of the engines is effected by a large steam and hydraulic engine on the direct acting principle. The crankshaft, a ponderous piece of machinery, is built up, and, together with the paddle shafts, is forged of mild steel and bored hollow. The paddle wheels are of large dimensions, each having three sets of arms. The wheels are of steel and constructed on the feathering principle, with curved steel floats. Placed athwartships, between the cylinders and the supports for the shafting, is the condenser, which is of cylindrical form, the condensing water being supplied by a separate centrifugal circulating pump worked by an independent steam engine, which pump is also arranged so as to clear the bilges of water in case of a serious leak. The feed pumps, two in number, made by Messrs. Weir, of Glasgow, are also independent of the main engines, and are each capable of supplying the boilers with water when working at full power.

Steam is supplied from four double-ended boilers, arranged in two compartments, one forward and one aft of the engine room, with two funnels. The boilers are of the multitubular return tube marine type, having eight corrugated furnaces in each, and constructed entirely of steel, to stand a working pressure of 140 lb. per square inch and fulfill the requirements of Lloyd's and the Board of Trade. They are adapted to work with Messrs. Howden's system of forced draught and the necessary fans and engines are fitted to supply heated air to the furnaces. The engines indicate about 10,000 horse power.

The condenser is cylindrical, and placed athwartships between the cylinders and the supports for the shafting, and the condensing water is supplied by a circulating pump worked by an independent steam engine.

The paddle wheels are made of steel, and constructed on the feathering principle, with curved floats. The floats are each 18 feet in length. Steam is supplied to the engine by four double-ended boilers arranged in two compartments, one forward and one aft of the engine room. They are adapted to work with Messrs. Howden's system of forced draught.

The vessel has two funnels and two pole masts, and presents a very handsome and majestic appearance.

On July 8, the "Empress Queen" made four trial runs between the Cloch and Cumbrae Lights, when she averaged over 22 knots per hour, and, considering the stormy weather which prevailed on that day, the result was gratifying. The following Monday a six hours' sea trial was carried out on the Clyde with equal success, the average speed over the whole course out to sea being 22 knots. While on her trials on the Clyde the highest speed attained was fractionally less than 23 knots an hour.

The "Empress Queen," which is licensed to carry 1,994 first and second class passengers by the Board of Trade, is now running to and from Liverpool and Douglas, which will be her regular station.

REVOLVING BULKHEAD DOOR.

A DOOR for watertight bulkheads has now been introduced and put to practical use by Mr. William Kirkaldy, of Glasgow. It has been fitted into the new channel steamer Duchess of Devonshire, and has received the approval of the Board of Trade. There can be no doubt that this supplies a desideratum for steamers with safety bulkheads. It consists of a hollow cylindrical casing which is bolted to the bulkhead, one-half of the cylinder being in one compartment and the other half in the compartment adjoining. The casing has a doorway into each compartment. Within the casing is a close fitting hollow cylinder which easily revolves, and having one doorway of a size corresponding to the doorways in the casing. This inner cylinder is suspended by a central bolt overhead, and revolves freely on ball bearings. When it is intended to pass through the bulkhead, the opening in revolving cylinder is brought round to correspond with the doorway in the casing. The person enters and turns the cylinder until the opening corresponds with doorway on the other side. And thus the doorway by which entrance was obtained to the casing is absolutely closed before the cylinder is so far revolved as to give egress from the door on the other side. The casing is bored like an ordinary engine cylinder, and the inside cylinder turned to fit it accurately. It is evident that this door cannot be left open at any time, for one opening must be absolutely closed before the other is opened. The only point in its construction that we are doubtful about is the tightness of the inner cylinder around the casing. If it is made to fit as perfectly as to be watertight, or nearly so, it will not be easily made to revolve, and a loose or easy fit will not serve. We think some arrange-

ment for insuring absolute watertightness, without involving much friction, would be desirable, and would not be difficult to devise.

We are indebted to The London Engineer for the above particulars.

ROPE TRANSMISSION.*

Leaving out of consideration the use of wire rope, which has a limited application, there are two general ways of transmitting power by rope, usually known as the "English system" and the "American system." It is the purpose of this paper to refer only briefly to the former, and treat more particularly of the American system, which is practically a development of the last ten years, and is gaining in favor and use daily, not only in this country, but also abroad.

The English system, probably so known from its extensive employment in the mills and factories of England, has been in familiar use for a great many years. It has been by no means confined to England, and there are many notable drives of the kind in this country, particularly in New England mills and in street railway power houses. The driving and driven pulleys are grooved and the power is transmitted by as many independent endless ropes as may be necessary. The weight of the ropes is depended upon to give the necessary adhesion in the grooves, just as in the case of wire rope transmission; but these are made V shaped and of such size that the rope does not touch the bottom, but gets a very much increased frictional adhesion from the tendency to wedge in the grooves. Almost

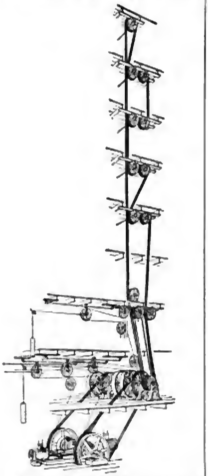


Fig. 1.—ROPE TRANSMISSION—ALL THE STRANDS OF THE DRIVE WRAPPED SUCCESSIVELY AROUND EACH DRIVEN SHEAVE.

universal practice seems to have adopted the angle of 45° for the sides of the groove as giving a sufficient grip for practical purposes, without undue tendency to squeeze the rope out of shape. It is a mistaken notion that many people seem to have that there is a loss of power in pulling the ropes out of the grooves as they leave the sheaves. With 45° or with even a sharper angle, there is no appreciable disposition on the part of the ropes to stick in the grooves and follow the sheaves.

The English or separate rope system has certain disadvantages which are largely overcome in the American plan. Owing to the practical impossibility of getting all the ropes of precisely the same length, some of them are always doing more than their proper share of the work. This tends to stretch them and reduce their diameter, causes a differential action and slipping, all of which operates to wear out the ropes. Various devices have been tried to equalize the strain on the ropes, one of the simplest being the use of grooves having slightly curved instead of straight sides. This makes the angle of the groove different at every point and equalizes the grip of the ropes which lie higher or lower in the groove, according to their variations in diameter. In designing drives by this system a liberal allowance has to be made for the certainty that the power is not going to be uniformly borne by the ropes; that is, some of them will be doing more than their proportion of the work; and, furthermore, that each rope is weakened by a splice. This places the separate rope system at a disadvantage in the matter of first cost of the installation. While the splice is not of necessity a cause of trouble, it is more liable to give trouble than any other part of a transmission, and the multiplication of them in this system is not a desirable feature. The American system, for all practical purposes, overcomes the difficulties cited above. One continuous rope is employed, wound spirally back and forth, around driving and driven sheaves as many times as necessary, one of the wraps in its course being taken around a tension carriage or tightener. The driven sheaves may be several in number and variously located with reference to the driver, as shown in Figs. 1 and 2. In the former, power is distributed to several points by wrapping all the strands of the drive successively around each driven sheave. In the latter one or more strands, as may be needed for the required power, are used at each point. This plan requires less rope and fewer bends in it, but the amount of power that may be utilized at each point is limited; while in the former plan it may be varied at will. The tension carriage is automatic in its action, and is to the system what the governor is to an engine. It insures a uniform amount of work being performed by each wrap of the rope, and is properly weighted to give the desired driving force and to take care of the variations in length, due to changes in temperature, moisture, etc.

The sheaves used in this system are grooved similarly to those previously referred to, the general angle being 45°. As a matter of practice, it will be observed that these are far from being so deep as in the English system; that is, the ridges between the grooves ordinarily

Fig. 2.—ROPE TRANSMISSION—ONE OR MORE STRANDS, AS NEEDED, USED AT EACH POINT.

project but a little above the pitch line or line of contact with the rope, instead of coming some little distance beyond or outside the ropes. This may be noteworthy as bearing silent testimony to which system operates the more smoothly, as in a properly designed transmission there should be no need of a deep groove to keep the ropes from jumping out. It is of the utmost importance that all of the grooves in a sheave should be exactly alike and of the same exact circumference; otherwise there will be a differential action set up between the ropes. Manufacturers who make a specialty of rope transmissions should have special gages and devices for calipering and measuring the circumference of the grooves to insure this accuracy, but it has been the writer's observation that this most important feature does not receive the attention it should. It has been emphasized by the unsatisfactory performance of wooden sheaves, where the impossibility of preventing the uneven wearing of the grooves has caused their abandonment, after they have done much to discredit the American system of rope transmission.

The diameters of the sheaves should always be as large as convenient; it is very poor economy to reduce the first cost of a drive by using small sheaves. Forty diameters of the rope should be the rule and thirty diameters the minimum size. It is well to observe as nearly as possible the same proportions for idlers. Even where they only carry the rope, it has to conform to their circumference for the moment it is upon them. This consideration is, perhaps, more theoretical than practical, and it may be better at times, where the spans are short, to make the idlers smaller to reduce their weight and insure their keeping up to the full speed of the rope. For this same reason they should have the V shaped groove. Round grooves in the rope bottoms are often used, but there is apt to be more or less slipping with these, especially in starting up, and consequent abrasion.

Various methods have been employed in the manufacture of sheaves, the object sought being to obtain perfectly true, uniform and smooth grooves, with the minimum machining, or without any at all. Wooden grooved sheaves have been used to a very considerable extent, and, as said, been discredited; casting the grooves in chills gave great promise, but was abandoned after a costly series of experiments; corrugated steel rims have been tried; and an excellent sheave has been made or "built up" of separate grooved rings bolted together, as many of the rings as necessary having arms and hubs, and being really complete single grooved sheaves. Fig. 3 shows two drives having this kind of sheaves, the driving and driven shafts in these drives being at right angles. This type of sheave is made in a special flask, with provision for ramming the sand very compactly in the grooves, the latter coming out of the sand so true and clean that they are merely smoothed a little with emery for a finish. The best and most economical sheaves made to-day are molded by particular machinery made for that purpose, and come from the foundry almost true and smooth enough to be used without machining, though a light cut is usually taken.

The tension carriage is a most important element of the drive. It should adjust itself automatically to the proper inclination. It is obvious that as the rope is wound spirally on the sheaves, it must be led back from the last groove of one of them to the first, otherwise it would run off the sheaves entirely. The tension carriage sheave is set at the proper inclination to accomplish this, as illustrated in the dynamo drive shown in Fig. 4. It must take care of all the minor inequalities and variations in the sheavs and rope, as well as provide the proper back pull for the required driving force, hence the carriage should be on good sized rollers, so as to be sensitive and immediate in its action. Sufficient travel should be provided for it to take up about one-fortieth of the length of the rope. This operation is often reversed, and I have frequently known tension carriages to be drawn up as far as possible by the shrinkage of the rope after a heavy rain or period of wet weather. The weight used should be only just enough to give the requisite driving force without slipping; any more than this only puts an unnecessary strain on the rope and shortens its life. The location of the tension carriage in the drive is as often determined by convenience as anything else. It may be horizontal, vertical or inclined. Two things must be kept in mind, however—it must be on one of the slack ropes, and if the particular slack rope cannot conveniently be taken from the driver directly around the tension sheave, but for convenience of location must be led around the driven or some other sheave, it must be taken around a loose groove, so that it may lead directly to the tension carriage without interference. I have frequently seen both of the above points wholly disregarded, both by manufacturers, who profess to make a specialty of rope transmissions, and by engineers of high standing.

The final element of transmission is the rope. In the

* A paper read before the Western Society of Engineers by Stanton B. Peck, Mem. Am. Soc. Mech. Engrs.

English system cotton ropes are generally used. This is probably from force of habit, as these drives were first introduced in textile mills, where cotton was a familiar article. It is, however, well adapted for drives of this kind, because it has comparatively little elasticity and does not stretch, hence it is easier to keep the ropes of uniform length than with hemp or manila. This rope is made somewhat peculiarly; it has four strands twisted together in the usual way, but each strand consists almost entirely of a bundle of yarn laid parallel with practically no twist. Each of these four bundles of yarn is wound spirally with some quite small bundles, which serve as binders and as a protection. This is what is known as the Lambeth brand of rope. It is very pliable and the friction of the soft cotton yarns on each other is less destructive than with manila; but the latter is much stronger than cotton and is almost universally used in the American system.

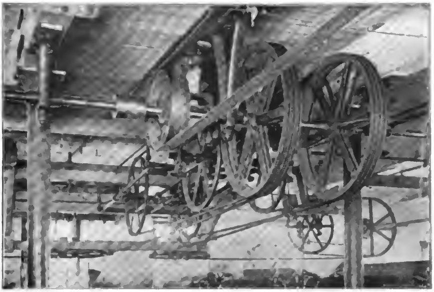

FIG. 3.—TWO DRIVES WITH BUILT UP SHEAVES.

Manila rope for the transmission of power should be made especially for that purpose. The twist should be looser than with ordinary ropes; only the longest and best fibers should be used and selected so as to be of uniform size for the same rope. These are laid up as the rope is made, in tallow, which acts as an internal lubricant and also protects the fiber from moisture. Graphite is sometimes used also in addition to the tallow, and assists in preventing internal chafing, but there is great difficulty in making the splice hold in such a rope. The best transmission rope, as shown by a series of tests, is made as above described, laid up in tallow merely and distinguished by a red yarn running through it. Up to one inch and a quarter three strands are used, and above that four. The four strand rope is the better shape, as being more nearly round, but in the smaller sizes the strands are so small that they do not make so good a splice. While not absolutely necessary, external dressings applied at intervals to the ropes are desirable, especially for outdoor drives, and where the rope is exposed to a hot, dry atmosphere. These dressings are made of varying proportions of such ingredients as tallow, graphite, pine tar, linseed oil, cottonseed oil, molasses, resin, etc. One very conveniently applied dressing is made in the form of sticks about 18 inches long and three inches in diameter, which are held against the rope while it is running.

Ropes of rawhide gave great promise a few years ago, and a number were put in use; most of these have been replaced with manila. Rawhide rope has great flexibility, and having comparatively few strands, is better able to stand internal and external friction, as there are no small yarns to chafe and break. Its most frequent use was for dynamo drives and where small sheaves were necessary. The great elasticity causes a good deal of whipping and slapping, and it is very difficult to make a splice hold; furthermore, the first cost is several times that of manila, and as it has not shown a proportionately greater durability to justify this, it is probable rawhide will never be used to any great extent.

As I said above, the splice is the weakest part of the drive. Correctly made, however, and in a properly designed drive, it should never give any trouble. As a matter of fact, much of the trouble caused by the failure of splices is due to the prevailing notion that any kind of a splice will answer. The ordinary sailor's splice, or the short splice, which is perfectly satisfactory for hauling or hoisting ropes, is quite inadequate for transmissions. The splices suitable for the latter are variously known as the English splice, or the long splice, and are from 80 to 150 diameters of the rope in length. Various mechanical splices have been tried, but most of them have had a very limited use. One objection to them is that they give way without warning, whereas the ordinary splice usually attracts attention by beginning to unstrand in ample time to prevent any damage.

Leaving the subject in its details and considering its general application, the availability for long transmissions, and especially for outdoor drives, is at once apparent. Fig. 5 illustrates a drive of this kind. By the use of rope the highest economy may be secured in large manufacturing and industrial establishments, as it becomes possible to distribute the power from one central power house. It is unnecessary before this society to dwell upon the desirability of such an arrangement as compared with the old way of having engines, and perhaps boilers, scattered all over a plant.

In Fig. 6 the engine is in the basement of building not shown, to left of the cut. The power is carried up through the roof, across the alley and down, where a portion is transmitted to a line shaft projecting through first building shown in cut, and the balance carried on to the building shown on the right.

In vertical drives, and in main drives from the fly-wheels of engines, it is well known that there is excessive journal friction from the tightness at which belts must be kept in the former case and from their great weight in the latter. Much of this is saved by the use of ropes, besides the advantage of a much quieter and smoother running drive. It is not at all uncommon to find fifteen or twenty per cent. of the power absorbed by journal friction and the stiffness of heavy main belts. A properly designed rope drive of the American system does not absorb more than four or five per cent. As it is not good practice to require a single tension carriage to take care of more than about eight or ten wraps of rope, these main drives are usually made up of two or more drives side by side exactly alike, each having its own rope and tension carriage. A plan sometimes employed is to wind the ropes in pairs, treating a pair of ropes precisely as though it were a single rope. Although there are some successful drives running in this way, this plan is not to be commended, as the two ropes on the tension carriage do not permit it to properly control either. An advantage of dividing main drives, as noted above, is that a portion of them may be run independently, or repaired while the balance of the drive is running.

In crossed, quarter-twist and mule stand drives, the flexibility of rope and the ease with which it may be led around the corners make a very appreciable saving of the large percentage of power that is wasted in overcoming the stiffness of belts under similar conditions.

Freedom from slipping makes rope particularly suited for dynamo drives for electric lighting, assuring a steadier current. I recall in this connection an incident where the basement of a large office building was partially flooded by continued heavy rains. Several of the dynamos were driven by belts, and were at once rendered inoperative, while those that were driven by ropes gave uninterrupted service.

The speed at which ropes are run with ranges from 1,000 to 5,000 ft. per minute. I have known of drives running successfully as high as 8,000 ft. Above 5,000 ft. a little figuring, using the ordinary formula, will show that centrifugal force, tending to throw the rope out of the grooves, becomes an important factor. Experience would seem to show, however, that practically it does not act as rapidly to diminish the driving force as it is theoretically supposed to. Its action can be counteracted by additional weight on the tension carriage, so that I have no doubt but what successful transmissions could be employed at a rope speed as high as 10,000 ft. per minute, or more, although the

FIG. 4.—TENSION CARRIAGE SHEAVE IN DYNAMO DRIVE.

FIG. 7.—METHOD OF CARRYING OUTDOOR DRIVE.

wear of the rope would be rapid. The best speeds are from 2,500 to 4,500 ft. per minute.

The use of winder sheaves is occasionally resorted to to give additional frictional adhesion, at both driving and driven ends of a transmission. That is, the rope in passing from driver to driven is wrapped one or more times as may be necessary around another sheave near the driver before being led around the driven, and wrapped around a similar sheave near the driven, before returning again to the driver. This is done in the drives in Fig. 3. It is a familiar device employed in all cable street railways. The advantage derived is not as great as might appear at first sight, as the tax upon the rope is greater from the frequent bending, and from the increased strain put upon the fewer number of ropes that transmit the power. This device may be used to advantage, however, in very long transmissions, as it reduces the amount of rope and the number of grooves to the carrying idlers; and also in drives where there is a great disparity in size between the driving and driven sheaves. I have in mind a successful transmission in an electric lighting station where the driving wheel is an engine flywheel 20 feet in diameter, and the driven sheave but a short distance away, 34 inches in diameter. The loss of arc of contact on the driven sheave is compensated by wrapping the rope four times around each of two rewinders at the driven end, giving the driven sheave practically 20 grooves to 12 in the driver. In drives of this kind care must be taken not to place the rewinder too near the sheave, as there may not be sufficient elasticity in the strands of rope to equalize the differential action set up by the unavoidable inequalities in the size of the rope and the grooves of the sheaves, and an excessive strain is produced on the shafts. The writer was once called upon to examine eight drives, about 300 ft. long each, where the power was transmitted by two $1\frac{1}{2}$" ropes and six wraps taken around a winder at each end of each drive. These winders were set so close to the main shaft that several of their shafts, which were $3\frac{1}{4}$" in diameter, were broken and all more or less badly sprung. A somewhat similar experience was met with by parties endeavoring to drive a street railway car by wrapping a continuous rope from sheave on central armature shaft six times around each axle and finally around a tension carriage. It was found that while the truck could be readily pushed by two men, with the ropes on it took about 40 H. P. to move it.

FIG. 5.—METHOD OF CARRYING OUTDOOR ROPE DRIVE.

FIG. 6.—ROPE DRIVE CROSSING ALLEY AND SERVING TWO BUILDINGS.

There are three questions that are constantly asked about rope transmissions: what powers will the various sizes of rope transmit at given speeds, how long will the rope last, and what is the cost relative to other modes of transmission? Unfortunately, a clean-cut, decisive answer cannot be given to any of them. There have been tables published giving the horse powers of different sizes of rope at various speeds, but none by any one who has had the experience that would make such a table reliable. Many things have to be taken into consideration in designing a transmission. Large sheaves and a few wraps of comparatively large ropes should be used in preference to small ropes and many wraps. Excessive speeds, reverse bends and frequent turns should be avoided as far as possible. In no small number of cases, however, the exigencies of the situation necessitate some one or more conditions that are unfavorable, and it is obvious that the work demanded of the rope should vary, as experience has shown the conditions to be more or less unfavorable. As an average illustration, however, of its transmitting power, it may be said that under ordinary conditions and at a speed of 2,500 feet per minute 1" rope will satisfactorily transmit 12 horse power, $1\frac{1}{2}$" rope 26 horse power, and 2" rope 48 horse power. It must always be borne in mind that the durability of the rope must be kept sight of as well as the actual transmitting power. This varies very greatly. Drives put in on the English system, using cotton ropes, are numerous where the ropes have lasted ten to twenty years. These drives, however, all have ropes two inches or more in size, and very large sheaves proportionately. It may be said that the average life of ropes of medium size is upward of five years. A great many that were put in more than five years ago are still giving good service to-day, so that as a matter of fact the system has hardly been in use long enough to determine what would be a fair length of service to expect. The small ropes, under unfavorable conditions, often have to be renewed annually. I know of one concern running a $\frac{3}{4}$" rope at high speed on a 9" sheave, who put on a new rope every three weeks, yet are perfectly satisfied with the transmission, which is the most successful means ever found to accomplish the purpose.

In the matter of comparative cost of rope and other transmissions, it can only be said that the grooved sheaves are considerably more expensive than plain pulleys, and there is the additional cost of the tension carriage; while, on the other hand, rope is very much cheaper than belting. From this it can be inferred that short drives of belts are the cheaper, while long drives of rope have the advantage in first cost, and increasingly so as the distance between centers increases. Again, with heavy main drives, from flywheels to jack shaft the large leather belts are so expensive that even with comparatively short centers the rope transmission is the cheaper.

I will only add in conclusion that rope transmission should be designed with intelligence and judgment based on experience. Where this is done they are certain to prove efficient and economical. The idea that because a rope is so flexible and so simple a thing it is bound to run all right, no matter what is done with it, is a mistaken one, and is largely responsible for any mistakes that may have been made or prejudices created against this most modern and satisfactory means of transmitting power.

THE VALUE OF MACHINERY AS AN INDUSTRIAL LEVER.
